Foreword

Separation science was first recognized as a distinct area of physical and analytical chemistry in the 1960s. The term was first coined, I believe, by the late J. Calvin Giddings, Research Professor at the University of Utah. Calvin Giddings recognized that the same basic physical principles governed a wide range of separation techniques, and that much could be learnt by applying our understanding of one such technique to others. This was especially true for his first loves, chromatography and electrophoresis and latterly field flow fractionation. Of course there are many separation techniques other than chromatography, many with a history at least as long, or indeed longer, than that of chromatography: distillation, crystallization, centrifugation, extraction, flotation and particle separation, spring to mind. Other separation techniques have emerged more recently: affinity separations, membrane separations and mass spectrometry. Most people, a few years ago, would not have classed mass spectrometry as a separation technique at all. However, with modern ionization methods, which minimize fragmentation, mixtures of compounds can first of all be separated and then each component identified through fragmentation by secondary ion-molecule collisions and further mass spectrometry. With the scale of mass spectrometry now matching that of microseparation methods such as capillary electrophoresis and capillary electrochromatography, combinations of orthogonal methods can now provide extremely powerful separation and identification platforms for characterizing complex mixtures.

Basically, all separation techniques rely on thermodynamic differences between components to discriminate one component from another, while kinetic factors determine the speed at which separation can be achieved. This applies most obviously to distillation, chromatography and electrophoresis, but is also obvious in most of the other techniques; even particle size separation by sieving can be classified in this way. The thermodynamic aspect is, of course, trivial being represented by the different sizes of the particles, as indeed it is for the size exclusion chromatography of polymers. However, the kinetic aspects are far from trivial. Anyone who has tried to sieve particles will have asked the question: is it better to fill the sieve nearly to the top and sieve for a long time, or is it better to dribble the material slowly into the sieve and just remove the heavies from time to time? One might further ask: how does one devise a continuous sieving process where large particles emerge from one port of the equipment, and small ones emerge from the other port? And how does one optimize throughput and minimize unit cost?

The publication of this *Encyclopedia of Separation Science* is a landmark for this area of science at the start of the third millennium. It will undoubtedly be of enormous value to practitioners of separation science looking for an overview and for guidance as to which method to select for a new problem, as well as to those who are at an early stage, simply dipping their toes into the waters, and trying to find out just what it is all about. Most important of all, by providing a comprehensive picture, it advances the whole field of separation science and stimulates further work on its development and application. The publishers, their editors and their authors are to be congratulated on a splendid effort.

John H. Knox
Edinburgh
8 March 2000

Preface

The ability to perform separations for the analysis, concentration or isolation of substances present in mixtures (of varying degrees of complexity) is arguably fundamental to the maintenance of our technological civilization. Separations can also be rather difficult to define, and over the course of a number of debates where we tried to ‘separate the wheat from the chaff’, we defined separations for the purposes of this work as ‘*processes of any scale by which the components of a mixture are separated from each other without substantial chemical modification*’. Of course some of the processes that are used in separations have a very long history, and the terms used to describe them are in widespread general use. So, we talk about how it is possible to distil wisdom, precipitate an argument, extract meaning and crystallize an idea and who can predict the future uses of the word chromatography? Whilst separations have been practised as an *art* for millennia, the last hundred years or so has seen the elucidation of the fundamentals that lie behind many of these processes. Thus, although separations are most widely used for achieving some practical objective, a firm theoretical understanding has been put into place that does allow the use of the term *separation science*. We have tried here to reflect the theoretical and practical aspects of the topics in this encyclopedia, and have attempted to achieve a blend of theory, practice and applications that will enable someone knowledgeable in a field to go directly to a relevant article; whilst the novice can begin with an overview and gradually iterate towards the practical application.

One thing is clear, separations cover such a wide range of topics that no single individual can be knowledgeable, let alone expert, in them all. It is against this background that we decided that an encyclopedia designed to cover this science would be of value as a single source of reference that would provide access to the whole field of separations.

For the purposes of defining the scope and coverage of the encyclopedia we have divided the area of separations into 12 families, or topic areas, using separation principles based on affinity, centrifugation, chromatography, crystallization, distillation, electrophoresis, extraction, flotation, ion exchange, mass spectrometry, membranes and particle size. Whilst there is no doubt that different editors might have grouped these slightly differently, they did not seem to us to be capable of further reduction. Taken together, we believe that they provide coverage of the whole field.

In preparing this multi-author and multi-volume work, all of the editors have been conscious of the gaps in their own expertise and the debt which they and the publishers owe to the Editorial Advisory Board, who to a large degree have compensated for the deficiencies in our own knowledge. Their help has been invaluable, as without them we would not have been able to achieve the necessary balance and it was, therefore, a source of particular sadness that one of them, Ted Woodburn, died prior to publication. Without Ted it is quite clear that the topic area of flotation would not have been so well covered, and we would like to think that he would have been well pleased with the finished work. We also hope that the masterly overview which he contributed to the encyclopedia, will be a lasting memorial to him. We are grateful to Jan Cilliers for stepping into the role of Editorial Board Advisor on flotation at short notice. We would also like to acknowledge the valuable input of G. J. Arkenbout at the beginning of this project, who was able to work with us for a short period of time before his death.

Assembling this knowledgeable and enthusiastic group of experts was a difficult task, and the editors would also wish to acknowledge the role of the Major Reference Works development team at Academic Press in this whole area, as well as thanking them for their assistance and patience throughout the project, from the initial planning to its final publication.

Finally, of course, we must acknowledge the contributions of the authors whose expertise constitutes this encyclopedia. Some of them have become firm friends in the period between the inception of this project and its completion. After all, separation science separates things but brings people together.

Ian D. Wilson, Edward R. Adlard, Michael Cooke, Colin F. Poole
Editors

Introduction

The need for separations as a means for performing the isolation, purification or analysis of substances, at scales ranging from tonnage quantities down to picograms or less, is an important feature of modern life. Such separations underpin virtually all aspects of research and commerce and indeed a vast industry has arisen to provide the equipment and instrumentation to perform and control these essential processes; indeed it is impossible to envisage our world without ready access to separations. To provide these capabilities a whole family of techniques has evolved to exploit differences in the physical or chemical properties of the compounds of interest, and to accommodate the scales on which the separations are performed. After all, a separation that works on the picogram scale based perhaps on capillary electrophoresis, may not easily be transferred to the gram scale and will be utterly impossible on the kilogram scale. In such instances an alternative type of separation, based on a totally different principle must be sought. And therein lies the problem—most scientists are specialists and while having an excellent knowledge of their own, often narrow, sphere of expertise are generally possessed of a much more hazy view of the capabilities and attributes of techniques outside that area. Even worse, such ignorance may persuade them to adopt an approach that is quite unsuited to the solution of the problem in hand.

The large number of articles in this encyclopedia, and the wide variety of the subject matter described in them, represents an attempt to provide separation scientists with a single authoritative source covering the broad range of separation methods currently available. Inevitably there is some overlap in places between articles dealing with closely related topics. However, in a work such as this where each article is meant to be a self-contained source of information, some overlap is unavoidable and not wholly undesirable in the context of ensuring full coverage of a topic.

The articles in the *Encyclopedia of Separation Science* fall into three categories as follows: ‘Level I’, which provides overviews of a particular separation area, e.g. flotation, distillation, crystallization, etc., written by acknowledged experts in the particular fields. These articles are presented with the aim of providing a wide ranging introduction to the topic from which the reader can then, if it seems appropriate, move on to ‘Level II’ articles.

Level II articles cover the theory, development, instrumentation and practice of the various techniques contained within each broad classification. For example the Level I article on chromatography is supported in Level II by descriptions of gas, liquid and supercritical fluid chromatography, together with information on instrumentation. Separations are, however, often of interest to practitioners because of their applications and Level II serves as an introduction to ‘Level III’.

Level III provides detailed descriptions of the use of the various methods described in Levels I and II for solving real problems. These might include articles on the various methods for extraction of pesticides or drugs from a matrix, with other articles on the chromatographic or electrophoretic techniques that could be used for their subsequent analysis. The extensive cross-referencing and exhaustive indexing for all of the articles in the work should enable the reader to obtain easily and rapidly all the relevant information in the encyclopedia. In addition, each article at whatever level contains a brief but carefully selected bibliography of key books, review articles and important papers. In this way the encyclopedia provides the reader with an invaluable ‘gateway’ into the separation science literature on a topic.

Lastly, because the importance of separation science lies in its value as an applied technique, we have commissioned a number of ‘essential guides’ to method development, in a limited number of key areas such as the isolation and purification of proteins and enzymes, etc., or the development of chromatographic separations.

While the techniques described in these volumes can in many cases be used as the basis of analytical methods, the emphasis of this work is on the methods of separation of mixtures, rather than their determination. For a treatise devoted to Analytical Science the reader is referred to the *Encyclopedia of Analytical Science*, also published by Academic Press, which can be considered to be complementary to the present work, in that it deals in depth with analysis rather than the application of separations.

The reader faced with the need to perform a separation, requiring information on a type of detector, or the use of a technique for a particular class of compound, etc., should therefore be able to look into the encyclopedia for information on that topic. Even where there is no information that is directly relevant to

the problem, it should still be possible to begin at Level I in order to determine the potential of a technique to solve the problem and then progress down through the levels until a solution begins to emerge.

The editors believe that, taken as a whole, this encyclopedia and its electronic version should provide a valuable source of knowledge and expertise for both those already skilled in the art of some aspect of separations and also for the novice. That, at least, is our hope.

This encyclopedia is a guide providing general information concerning its subject matter; it is not a procedure manual. The readers should consult current procedural manuals for state-of-the-art instructions and applicable government safety regulations. The publisher and the authors do not accept responsibility for any misuse of this encyclopedia, including its use as a procedural manual or as a source of specific instructions.

AFFINITY SEPARATION

Introduction

Of the collection of separation technologies known as 'affinity', affinity chromatography is by far the most widely used variant. Affinity chromatography is becoming increasingly important as the speed of the revolution taking place in biotechnology processing increases. The concept of an 'affinity' separation results from a naturally occurring phenomenon existing within all biological macromolecules. Each biological macromolecule contains a unique set of intermolecular binding forces, existing throughout its internal and external structure. When alignment occurs between a specific site of these forces in one molecule with the site of a set of forces existing in another (different) molecule, an interaction can take place between them. This recognition is highly specific to the pair of molecules involved. The interactive mechanism can be converted into a universal mutual binding system, where one of the binding pair is attached to an inert matrix, packed into a column and used exclusively to capture the other matching molecule. When used in this (affinity) mode, the technique is probably the simplest of all chromatographic methods. It is, however, restricted almost exclusively to the separation and purification of biological macromolecules, and is unsuitable for small molecules.

Affinity chromatography or bioselective adsorption chromatography was first used in 1910, but it was only in the 1960s that affinity chromatography as practised today was developed as a purification technique. By the late 1970s the emergence of recombinant DNA technology for the manufacture of protein pharmaceuticals provided a new impetus for this highly specific chromatographic method, implemented by the demand for ever-increasing product purity implicit in regulatory frameworks devised by (amongst others) the USA's Food and Drug Administration (FDA). Finally, the need to reduce the cost of drugs is under constant scrutiny by many Governments, particularly those with controlled health schemes funded by revenue raised by taxation. These mutually incompatible pressures indicate the need for more efficient separation systems; the affinity technique provides the promise of meeting all necessary requirements.

Separation and purification methods for biological macromolecules vary from the very simple to the esoteric. The type of technique adopted is basically a function of source, the fragility of the molecule and the purity required. Traditionally, high purity protein pharmaceuticals have used multistage processing, but this is very inefficient as measured by the well-documented fact that 50–80% of total production costs are incurred at the separation/purification stage. In contrast, the highly selective indigenous properties of the affinity method offer the alternative of very elegant single-step purification strategies. The inherent simplicity and universality of the method has already generated a wide range of separation technologies, mostly based upon immobilized naturally occurring proteinaceous ligands. By comparing the 'old' technologies of 'natural' ligands or multistage processing with the 'new', exemplified by synthetic designed ligands, the most recent advances in affinity processing can be described.

Biological Recognition

As nature evolved, life forms had to develop a protective mechanism against invading microorganisms if they were to survive. Thus there is a constant battle between the cell's defence mechanism and the attacking microorganisms, a battle resolved by the cells generating antibodies (the immunoglobulins) able to recognize the protein coat of attacking microorganisms and signal killer cells to destroy the invaders before they cause harm to the host. Equally, if microorganisms were to survive, they had continually to mutate and change their protein coats to avoid detection by existing antibodies. The 'attack and destroy' process is a function of changes in the molecular structure in a specific part of the protein, with only the most minute of changes occurring at the surface of the protein. Evolution has thus designed a system where every protein has a very precise structure, but one which will always be recognized by another. One element of the interacting pair can be covalently bonded onto an inert matrix. The resulting chromatographic medium can then be packed into a column, and used to separate exclusively its matching partner from an impure mixture when added as a solution to the top of the column. This fact can be stated as follows – *for every protein separation problem there is always an affinity solution*. The process of producing a satisfactory medium is quite difficult.

The matching pair must be identified, and one of them isolated in a pure form. Covalent bonding onto an inert matrix in a stable manner must always allow the 'docking' surface of the protein to be positioned to make it available to the target protein. The whole also has to be achieved at an acceptable cost.

This technique has resulted in many successful applications, often using antibodies as the affinity medium (immunoaffinity chromatography), but large scale separations using these 'natural' ligands are largely restricted by cost and regulatory reasons. Although immunoaffinity chromatography is still widely practised, in recent years the evolution of design technologies has provided powerful new approaches to mimic protein structures, resulting in the development of synthetic ligands able to work in harsh operational environments and at low cost.

The Affinity Process

The affinity method is critically dependent upon the 'biological recognition' existing between species. By permanently bonding onto an inert matrix a molecule (the ligand) that specifically recognizes the molecule of interest, the target molecule (the ligate) can be separated. The technique can be applied to any biological entity capable of forming a dissociable complex with another species. The dissociation constant (K_d) for the interaction reflects the complementarity between ligand and ligate. The optimal range of K_d for affinity chromatography lies between 10^{-4} and 10^{-8} mol L⁻¹. Most biological ligands can be used for affinity purposes providing they can be immobilized, and once immobilized continue to interact successfully with their respective ligates. The ligand can be naturally occurring, an engineered macromolecule or a synthetic molecule. Table 1 provides some examples of immobilized ligands used to purify classified proteins. The

affinity method is not restricted to protein separations; nucleic acids and whole cells can also be separated.

The simplicity of the chromatographic process is shown in Figure 1. The ligand of interest, covalently bonded onto the inert matrix, is contained in the column, and a solution containing the target (the ligate) is passed through the bed. The ligand recognizes the ligate to the exclusion of all other molecules, with the unwanted materials passing through the column packing while the ligate is retained. Once the bed is saturated with the target molecule (as measured by the breakthrough point), contaminating species are washed through, followed by collection of the target molecule as a very pure fraction using an eluting buffer solution. Finally, the column is cleansed from any strongly adsorbed trace materials, usually by regeneration with a strong alkali or acid, making it available for many more repeat runs. An outstanding advantage of the affinity process is an ability to concentrate very dilute solutions while stabilizing the captured protein once adsorbed onto the column. Many of the in-demand proteins manufactured by genetically engineered microorganisms are labile, allowing only minute quantities to be present in the fermentation mix before they begin to deteriorate. An ability to capture these very small quantities while stabilizing them in the adsorbant phase results in maximization of yield, making massive savings in total production costs.

Although the technical processing advantages are clear there is a major difficulty in the application of affinity chromatography as understood by most practitioners today. Most ligands described in Table 1 suffer from two primary disadvantages: a lack of stability during use; and high cost. Fortunately these problems have now been overcome, and affinity chromatography is now accepted as the major separations technology for proteins.

Table 1 Affinity ligands and purified proteins

<i>Immobilized ligand</i>	<i>Purified protein</i>
Divalent and trivalent metal ion	Proteins with an abundance of his, try and cys residues

Proteins A and G	Immunoglobulins
Hormones, drugs	Receptors
Antibodies	Antigens
Antigens	Antibodies

Figure 1 Schematic diagram of affinity chromatography.

Matrices

By definition matrices must be inert and play no part in the separation. In practice most play a (usually) negative role in the separation process. To minimize these disadvantages matrices have to be selected with great care. There is a theoretically perfect matrix, defined as consisting of monodispersed perfectly shaped spheres ranging from 5 to 500 μm in diameter, of high mechanical strength, zero nonspecific adsorption and with a range of selectable pore sizes from 10–500 nm, a very narrow pore size distribution and low cost. This idealized matrix would then provide the most efficient separation under all experimental conditions. As always, a compromise has to be reached, the usual approach being to accentuate the most attractive characteristics while minimizing the limitations, usually by manipulating the experimental conditions most likely to provide the optimum result.

The relative molecular masses of proteins vary from the low thousands to tens of millions, making pore size the most important single characteristic of the selected matrix. Very large molecules need very open and highly porous networks to allow rapid and easy penetration into the core of the particle. Structures of this type must therefore have very large pores, but this in turn indicates low surface areas per unit volume, suggesting relatively low numbers of surface groups to which ligands can be covalently attached. The matrix must also be biologically and chemically inert. A special characteristic demanded from biological macromolecular separations media is an ability to be sanitized on a routine basis without damage. This requires resistance to attack by cleansing reagents such as molar concentrations of strong alkali, acids and chaotropes. In contrast to analytical separations, where silica-based supports are inevitably used, silica cannot meet these requirements and is generally not favoured for protein separations. Table 2 contains examples of support matrices used in affinity separations.

The beaded agaroses have captured over 85% of the total market for biological macromolecule separations, and are regarded as the industry standard to which all other supports are compared. They have achieved this position by providing many of the desirable characteristics needed, and are also relatively inexpensive. Beaded agaroses do have one severe limitation – poor mechanical stability. For analytical applications speed and sensitivity are essential, demanding mechanically strong, very small particles. Beaded agaroses are thus of limited use analytically, a gap filled by high performance liquid chromatography (HPLC) using silica matrices. For preparative and large scale operations other factors are more important than speed and sensitivity. For example, mass transfer between stationary phase and mobile phase is much less important when compared to the contribution from the chemical kinetics of the binding reaction between stationary phase and protein. Band spreading is also not a serious problem. When combined with the highly selective nature of the affinity mechanism, these factors favour the common use of large sized, low mechanical strength particles.

In recent years synthetic polymeric matrices have been marketed as alternatives. Although nonbiodegradable, physically and chemically stable, with good permeabilities up to molecular weights greater than 10^7 Da, the advantages provided are generally offset by other quite serious disadvantages, exemplified by high nonspecific adsorption. Inorganic matrices have also been used for large scale protein separations, notably reversed-phase silica for large scale recombinant human insulin manufacture (molecular weight approximately 6000 Da), but are generally not preferred for larger molecular weight products. A very slow adoption of synthetic matrices is

Table 2 Support matrices

<i>Support matrix</i>	<i>Operational pH range</i>

PTFE	Unaffected

PTFE, polytetrafluoroethylene.

indicated as improvements are made to current materials and the prices of synthetics begin to approach those of agarose beads. Other factors resist any significant movement towards synthetic matrices. Most installed processing units are designed for low performance applications. Higher performance matrices would need reinstallation of new, much higher cost high performance plant; plant operators would need retraining; operating manuals would need rewriting; and plant and factory would need reregistration with the FDA. In combination, the implication is that penetration of high performance systems for large scale applications will be slow, and agarose beads will continue to dominate the market for protein separations.

Covalent Bonding

A basic requirement of all chromatographic media is the need for absolute stability under all operational conditions through many cycles of use. Consequently all ligands must be covalently bonded onto the matrix, and various chemistries are available to achieve this.

A number of factors are involved:

1. The performance of both ligand and matrix are not impaired as a result of the coupling process.
2. Most of the coupled ligand is easily accessible to the ligate.
3. Charged or hydrophobic groups are not generated on the matrix, so reducing nonspecific adsorption.
4. The immobilized ligand concentration is optimal for ligate bonding.
5. There is no leakage of immobilized ligand from the matrix.

Some ligands are intrinsically reactive (or can be designed to be so) and contain groups that can be

coupled directly to the matrix, but most require coupling via a previously activated matrix. The affinity matrix selected must have an adequate number of appropriate surface groups onto which the ligand can be bonded. The most common surface group is hydroxyl. The majority of coupling methods involve the activation of this group by reacting with entities containing halogens, epoxy or carbonyl functional groups. These surface residues are then coupled to ligands through primary amines, hydroxyls or thiol groups, listed in **Table 3**.

Polysaccharides, represented by agarose, have a high density of surface hydroxyl groups. Tradition still dictates that this surface is activated by cyanogen bromide, but it is well established that this reagent forms pH-unstable iso-urea linkages, resulting in a poorly performing product. Furthermore CNBr-activated agarose needs harsh coupling conditions if high yields of final media are to be obtained, suggesting high wastage of often expensive ligands. This factor is particularly evident with fragile entities such as the very-expensive-to-produce antibodies, and yet many workers simply read previous literature and make no attempt to examine alternative far superior coupling methods. The advantages of mild coupling regimes are demonstrated in **Figure 2**, where the use of a triazine-activated agarose is compared to CNBr-activated agarose. Yield is significantly increased, largely by coupling under acidic rather than alkaline conditions.

Intermolecular Binding Forces

Almost all chromatographic separations rely upon the interaction of the target molecule with either a liquid phase or a covalently bonded molecule on the solid phase, the exceptions being those relying upon molecular size, e.g. molecular sieves and gel filtration. In affinity separations ligates are inevitably

complex biological macromolecules or assemblies, mostly or exclusively consisting of amino acids entities linked together in a specific manner. This complexity of structure provides many opportunities to exploit the physicochemical differences between the target molecule and the ligand to be used. Each structure contains the four basic intermolecular binding forces – electrostatic, hydrogen bonding, hydrophobic and van der Waals interactions – spread throughout the structure in an exactly defined spatial manner. The degree of accessibility and spatial presentation within the pore of the medium, and the strength of each force relative to each other, dictate whether these forces are utilized to effect the separation. The biological recognition between species is a reflection of the sum of the various molecular interactions existing between them, and this summation is fixed for the ligate. However, various ligands may be found that emulate some or all of the available binding forces to various degrees.

Affinity adsorbents are therefore assigned to one of three broad ligand categories: nonspecific, group specific or highly specific. Nonspecific ligands have only a superficial likeness to biological ligands and binding is usually effected by just one of the four binding processes described above. Although ion exchange materials can be used in a similar manner to affinity adsorbents, they only exhibit the single force of electrostatic binding. They are thus limited to relatively indiscriminate binding. In this case the only criterion for binding is that of an overall charge.

Fortunately there are a vast number of biological ligands that can interact with more than one macromolecule and consequently group-specific ligands are commonplace. Since group-specific adsorbents retain a range of ligates with similar binding requirements, a single adsorbent may be used to purify a number of ligates. Group-specific ligates can be used when the desired ligate is present in high concentration, but this implies that some preprocessing has taken place and a concentration step interposed. The use of non/group-specific adsorbents can only offer partial separations. This results in having to apply several stages in series, each only capable of removing a proportion of the impurities. In contrast a highly selective ligand can exclusively remove the target in one step, but often the resulting complexes are very tightly bound, have low binding capacities, are easily denatured and are expensive to produce. Until recently these adsorbents were restricted to technically difficult isolations. Today the use of computer-assisted molecular modelling systems provides opportunities to investigate relationships between designed ligands and relevant protein structures. For the first time logical design approaches can be applied and consequently stable inexpensive ligands have now become available.

Analytical Scale-Up

Modern biotechnology uses two different types of chromatography. Analytical separations require that run time is minimized, while resolution and

sensitivity are maximized. In contrast, for preparative and process applications, the objective is to maximize purity, yield and economy. These techniques have developed separately, simply because biological macromolecules pose unique difficulties, making them unsuitable for 'standardized' analysis. A major influence on this division has been that scale-up usually occurs very much earlier in the development of a process, causing biochemists to turn to the traditional low performance methods of ion exchange (IE), hydrophobic interaction (HI) and gel permeation chromatography (GPC). The highly efficient affinity chromatography method was generally ignored, primarily because of the difficulty of having to develop a unique ligand for each separation rather than having 'off-the shelf' column packings immediately available from external suppliers. For analytical purposes high performance affinity liquid chromatography (HPALC) is a rarity, a function of the limited availability of suitable matrices (Table 2) and the affinity process itself.

Where quantifiable high speed chromatography is required, reversed-phase HPLC (RP-HPLC) has no equal. Unfortunately there is no general purpose method for biomolecules to parallel the inherent power of RP-HPLC. The success of RP-HPLC for analysis can be judged from the large number of published applications developed for the 'first wave' of protein pharmaceuticals manufactured by genetically engineered microorganisms. These extracellular (relatively) low molecular weight proteins include human insulin, human growth hormone and the interferons. However, as molecular size and fragility increase, so difficulties in using HPLC increase, a primary reason why much analysis is still conducted on low performance systems. Low performance systems are easily scaled up; RP-HPLC is not.

Biological separation systems must be aseptically clean throughout the process. The mixtures are inevitably complex and usually contain many contaminating similarly structured species. Such species can adsorb very strongly onto the medium, demanding post-use washing with very powerful reagents to sterilize and simultaneously clean the column. Silica-based matrices cannot survive this type of treatment, hence scale-up of analytical procedures is generally precluded. The first wave of commercial protein pharmaceuticals have generally proved to be relatively stable under high stress conditions. On the other hand intracellular proteins, often of high molecular weight, are unstable. Analysis by high performance RP-HPLC methods then becomes problematic. Demand for fast, high resolution, analytical methods will continue to increase for on-line monitoring and process validation. Such techniques have already been

used to determine degradation of the target protein (for example deamidated and oxidized elements); to identify previously unidentified components; to establish the chromatographic identity between recombinant and natural materials; to develop orthogonal methods for the identification of unresolved impurities; and for many other demanding analytical approaches.

Affinity versus Traditional Media

When projects are transferred from research to development two sets of chromatographic techniques are carried forward: analysis, usually based on RP-HPLC; and larger scale serialized separation steps, often incorporating traditional methods of ion exchange, hydrophobic interaction and gel permeation chromatography. Major decisions have to be taken at this juncture – to scale up the separation processes developed during the research phase or to investigate alternatives. Regulatory demand and shortened patent lifetimes compel managements to 'fast track' new products. Commercial pressure is at a maximum. Being first to market has the highest priority in terms of technical and commercial reward. Very little time is left to explore other separation strategies. It is known that serial application of IE, HI and GPC inevitably leads to very high manufacturing costs, but which comes first? Most often the decision is taken to begin manufacture using unoptimized separations as defined in research reports. It is only in retrospect that very high production costs become apparent. By then it is too late – regulatory systems are firmly in place.

There is an alternative. If researchers were more aware of process economics and the consequences of regulatory demand, selection of superior separation processes could then result. Although most researchers are fully aware of the advantages of single-step affinity methods, paradoxically the high selectivity advantage of affinity chromatography is also a weakness. Suitable off-the-shelf affinity adsorbents are often unavailable, in which case an adsorbent has to be custom synthesized. Since the majority of biochemists have no desire (or time) to undertake elaborate chemical synthesis, antibody-based adsorbents are commonly used. However, raising suitable antibodies and purifying them before immobilization onto a preactivated support matrix is an extremely laborious procedure. In addition, proteins are so often tightly bound to the antibody that subsequent elution involves some degree of denaturation and/or loss of activity. Ideal media require the incorporation of elements of both nonselective and selective adsorbents to provide adsorbents with a general applicabil-

ity. If stable, highly selective and inexpensive affinity ligands were available, then opportunities would exist for researchers to develop efficient high yield separations even in the earliest phases of investigation. These systems could then be passed forward to production with the knowledge that optimally efficient separations are immediately achievable.

Production costs of any pure material reflect the absolute purity level required and the difficulty of achieving it. Therapeutic proteins have high purity requirements and the larger the administered dose, the purer it has to be. Since many protein pharmaceuticals will be used at high dose levels, purities need to exceed 99%, occasionally up to 99.999%. That these purities can be met by traditional methods is possible, but it is widely documented that the application of such methods massively increases production costs. Between 50 and 80% of total production costs of therapeutic proteins are incurred at the purification stage. The manufacturing cost of a product is directly related to its concentration in the mother liquor; the more dilute it is, the higher the cost of recovery. Since traditional purification processes on their own cannot selectively concentrate a target protein to the exclusion of all others, they have to be used in series. The number of stages required can vary between four and 15. Each step represents a yield loss, and incurs a processing cost. Yields of less than 20% are not uncommon. **Figure 3** shows an enzyme purified in multiple stages and by a one-step affinity process.

It was these limitations that caused biochemists to examine highly selective ligands. Almost any compound can be used as an affinity ligand provided it can be chemically bonded onto a support matrix and, once immobilized, it retains its ability to interact with the protein to be purified. The ligand can be

a simple synthesized entity or a high molecular weight protein. The affinity technique is theoretically of universal application and any protein can be separated whatever its structure and origin. As always, there are major limitations. The most effective affinity ligands are other proteins. Unfortunately such proteins are difficult to find, identify, isolate and purify. This results in high costs. An even greater deterrent is that most proteins are chemically, catalytically and enzymically unstable, a particularly unattractive feature if they are to be used for the manufacture of therapeutic substances; and regulatory authorities generally reject applications using proteinaceous ligands.

In anticipating that one day stable inexpensive affinity media would be in demand, a team led by C.R. Lowe began an investigation into which synthetic ligand structures offered the greatest possibility of developing inexpensive stable ligands. It was concluded that structures that could be manipulated into specific spatial geometries and to which intermolecular binding forces could easily be added offered the highest chance of success. Model compounds were already available; the textile dyes.

Synthetic Ligands

Textile dyes had already proved to be suitable ligands for protein separations. Blood proteins, dehydrogenases, kinases, oxidases, proteases, nucleases, transferases and ligases can be purified by a wide variety of dyes. However, they did not prove to be the breakthrough so eagerly awaited. An essential feature of all chromatographic processes is exact repeatability from column to column, year after year. Textile dyes are bulk chemicals, most of which contain many by-products, co-produced at every stage of the dye

Figure 3 Comparison of multistep versus affinity separation.

manufacturing process. This fact alone makes reproducibility problematic. Furthermore, the bonding process between dye and matrix was poorly researched. This resulted in extensive leakage. All commercially available textile dye products leak extensively, especially under depyrogenating conditions (Figure 4). Despite these limitations, it was recognized that dye-like structures had a powerful underlying ability to separate a very diverse range of proteins. Their relatively complex chemical structures allow spatial manipulation of their basic skeletons into an infinite variety of shapes and configurations. Proteins are complex three-dimensional (3-D) structures and folds are present throughout all protein structures. An effective ligand needs to be shaped in such a manner that it allows deep insertion into a suitable surface fissure existing within the 3-D structure (Figure 5). In contrast, if the ligand only interacts with groups existing on external surfaces, then nonspecific binding results and proteins other than the target are also adsorbed. A much more selective approach is to attempt to insert a ligand into an appropriate fold of the protein, and add binding groups to correspond with those present in a fold of the protein. If all four of the basic intermolecular forces (Figure 5: W, electrostatic; X, hydrogen bond-

ing; Y, van der Waals; Z, hydrophobic) align with the binding areas in the protein fold, idealized affinity reagents result. The use of spacer arms minimizes steric hindrance between the carrying matrix and protein.

Figure 4 Leakage of blue dye from various commercial products. □, 0.1 mol L⁻¹ NaOH; ▨, 0.25 mol L⁻¹ NaOH; ■, 1 mol L⁻¹ NaOH. Key: A, Mimetic Blue 1 A6XL (affinity chromatography); B, Affi-Gel Blue (Bio-Rad); C, Blue Trisacryl-M (IBF); D, Fractogel TSK AF-Blue (Merck); E, C.I. Reactive Blue 2 polyvinyl alcohol-coated perfluoropolymer support; F, Blue Sepharose CL-6B (Pharmacia); G, immobilized Cibacron Blue F3G-A (Pierce); H, Cibacron Blue F3G-A = Si500 (Serva); I, Reactive Blue 2-Sepharose CL-6B (Sigma).

The final step is to design appropriate bonding technologies to minimize potential leakage. Until recently this type of modelling was a purely theoretical exercise. It was only the introduction of computer-assisted molecular modelling techniques that allowed the theory to be tested. Before the arrival of logical modelling the discovery of selective ligands was entirely based upon empirical observation, later followed by a combination of observation, experience and limited assistance from early computer generated models. Although several novel structures evolved during this period, a general approach to the design of new structures remained elusive. At this time only very few 3-D protein structures were available, again greatly restricting application of rational design approaches. As more sophisticated programmes, simulation techniques, protein fragment data and many more protein structures were released, logical design methods were revolutionized. However, many millions of proteins are involved in life processes, and it is clear that many years will elapse before the majority of these will be fully described by accurate models. Consequently intuition and experience will continue to play a major role in the design of suitable ligands. Of available rationally designed synthetic molecules, the Mimetic™ range can currently separate over 50% of a randomly selected range of proteins. Stability under depyrogenating conditions has been demonstrated for these products (Figure 6). This results in minimal contamination from ligand and matrix im-

purities, substantial increases in column lifetime, and improvements in batch-to-batch reproducibility.

Rational Design of Affinity Ligands

Modification of Existing Structures

The first example of a rational design of new biomimetic dyes used the interaction between horse liver alcohol dehydrogenase (ADH) and analogues of the textile dye Cibacron Blue F3G-A (Figure 7). It had been established that the parent dye binds in the NAD^+ -binding site of the enzyme, with the anthraquinone, diaminobenzene sulfonate and triazine rings (rings A, B and C, respectively, in Figure 7) apparently adopting similar positions to those of the adenine adenosine ribose and pyrophosphate groups of NAD^+ . The anthraquinone ring (A) binds in a wide apolar fold that constitutes, at one end, the adenine bridging site, while the bridging ring (B) is positioned such that its sulfonate group interacts with the guanidinium side chain of Arg271 (Figure 8). Ring C binds close to where the pyrophosphate bridge of the coenzyme binds with the reactive triazinyl chlorine adjacent to the nicotinamide ribose-binding site. The terminal ring (D) appears to be bound in a fold between the catalytic and coenzyme binding domains, with a possible interaction of the sulfonate with the side chain of Arg369. The binding of dye to horse liver ADH resembles ADP binding but differs significantly at the nicotinamide end of the molecule with the mid-point position of ring D displaced from the mid-point position of the nicotinamide ring of NAD^+ by about 1 nm. Consequently a number of terminal-ring analogues of the dye were synthesized and characterized in an attempt to improve the specificity of dye binding to the enzyme. Table 4 lists some of the analogues made by substituting -R in the D ring (Figure 7), together with their dissociation constants. These data show that small substituents bind more tightly than bulkier groups, especially if substituted in the *o*- or *m*-positions with a neutral or anionic group. Further inspection of the computer model given as Figure 8 showed that the dye analogues were too short and rigid to bind to horse liver ADH in an identical manner to the natural coenzyme, NAD^+ . Consequently analogues of the parent dye were designed and synthesized with central spacer functionalities to increase the length and flexibility of the molecule (Figure 9). This product proved to be some 10 times superior to any previously synthesized compound. This work provided the first proof that rationally designed molecules could be converted into stable, inexpensive, chromatographic media, while providing the most remarkable separations.

De Novo Design

Most early efforts in proving the rational design technology was based upon dye structures. To date all dyes considered have been anionic, presumably because the charged chromophores of these ligands

mimic the binding of naturally occurring anionic heterocycles such as NAD^+ , NAPD^+ , ATP, coenzyme A, folate, pyridoxal phosphate, oligonucleotides and polynucleotides. However, some proteins, particularly proteolytic enzymes, interact with cationic substrates. The trypsin-like family of enzymes forms

Figure 8 Putative binding pocket for the terminal-ring analogue ($m\text{-COO}^-$) of Cibacron Blue F3G-A in the coenzyme binding site of horse liver alcohol dehydrogenase (ADH). The site lies lateral to the main coenzyme binding site and comprises the side chains of two juxtaposed cationic residues Arg47 and His51.

one of the largest groups of enzymes requiring cationic substrates and includes enzymes involved in digestion (trypsin); blood clotting (kallikrein, thrombin, Factor Xa); fibrinolysis (urokinase, tissue plasminogen activator) and complement fixation. These enzymes possess similar catalytic mechanisms and bind the side chains of lysine or arginine in a primary pocket proximal to the reactive serine (Ser195), with specificity being determined partly by the side chain of Asp189 lying at the bottom of the pocket, and partly by the ability of the individual enzymes to form secondary interactions with the side chains of other nearneighbouring substrate amino acids. For example, tissue kallikrein differs from pancreatic trypsin in that it displays a marked preference for phenylalanine in the secondary site, probably because the phenyl ring on the phenylalanine residue neatly slips into a hydrophobic wedge-shaped pocket between the aromatic side chains of residues Trp215 and Tyr99 (Figure 10). Specificity for the secondary amino acid residue is less stringent in trypsin since Tyr99 is replaced by Ala99 and the hydrophobic pocket cannot be formed. By designing a mimic for the Ph-Arg dipeptide should result in a specificity for kallikrein. Figure 11 uses *p*-aminobenzamidine and phenethylamine functions substituted on a monochlorotriazine moiety. However, the active site of pancreatic kallikrein lies in a depression in the surface of the enzyme. The expected steric hindrance is eliminated

by insertion of a hexamethylene spacer arm between the designed ligand and the matrix. After synthesis of this medium it was demonstrated that purified pancreatic kallikrein was strongly bound, with over 90% of activity being recovered on elution with 4-aminobenzamidine, whereas trypsin appeared largely in the void of the column. This medium was able to purify kallikrein 110-fold from a crude pancreatic acetone powder in a single step.

There is an alternative to the rational design approach – the use of combinatorial libraries.

Combinatorial Libraries

The driving force behind the development of combinatorial libraries has been the many failed attempts to design therapeutic substances using theoretical knowledge allied to rational design; very few such approaches succeeded. In contrast, combinatorial library design is now thought by some to provide the best opportunity of discovering new novel peptides and small molecule structures for pharmaceutical application. A quite natural extension of the concept is to use combinatorial libraries to discover ligands capable of achieving highly efficient protein separations. When directed at drug discovery the earliest workers built libraries from peptides. For ligands libraries will generally utilize simple chemical molecules and occasionally smaller peptides. To distinguish this subsection from the earlier methods a convenient designation is the term Chemical Combinatorial Library (CCL)TM.

Although procedures for rationally designed ligands are well established, the newness of CCL suggests that CCL design of affinity ligands should be regarded as embryonic rather than immediately available for commercial application. There are thus two diametrically opposed systems – the rational design process, based on logic, experience and knowledge; and CCL which is illogical and completely random. One description of CCL is ‘a method of increasing the size of the haystack in which to find your needle’. A very recent approach is to combine both rational and CCL techniques, a process termed ‘intelligent’ combinatorial design. At the time of writing there are no published examples of ligands derived from CCL, although patents have been filed in this area.

Regulations and Drug Master Files

For researchers the relevance of regulations often seems remote, and yet the decisions taken in even the earliest stages of research can take on a great significance if the target product becomes a commercial

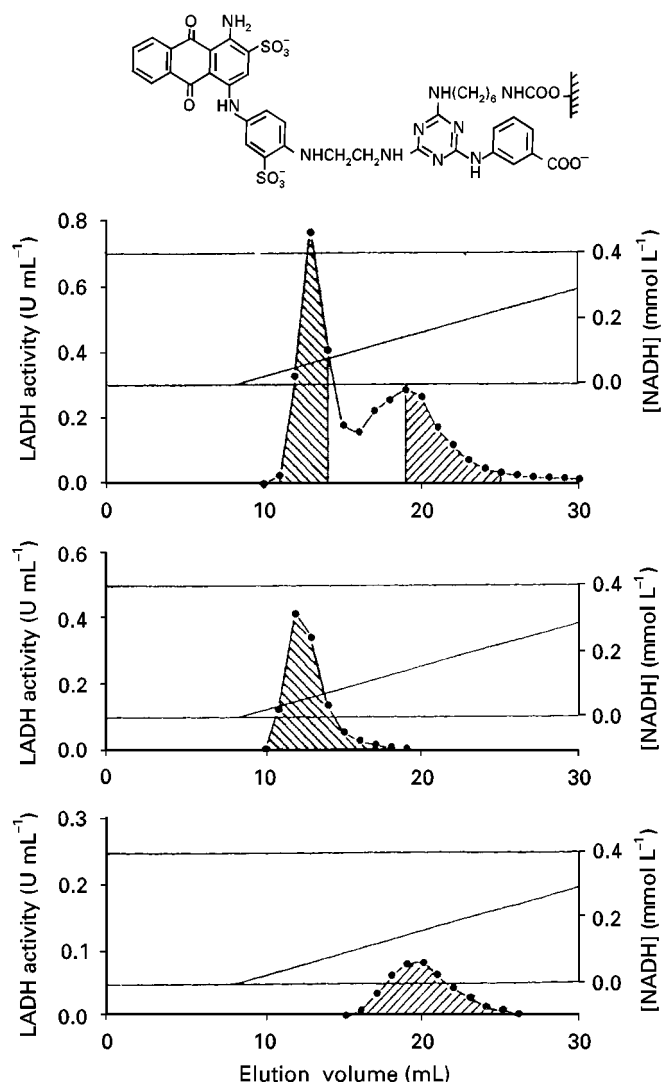

Figure 9 Horse liver alcohol dehydrogenase separation. Using the modified Cibacron Blue F3G-A (Figure 7) structure given above, the selectivity is greatly enhanced making it possible to separate the isoenzymes.

reality. It is regrettable that many researchers slavishly follow previously published data on a given separation problem without giving thought to the longer-term implications of their decisions. Sections above describe the adverse economic effects of multi-stage processing, but an equally important factor is regulatory issues. The most widely used regulations are those defined by the USA's Food and Drug Administration (FDA). Any company wishing to import products relevant to regulations existing in the USA must conform exactly to FDA requirements; drugs in particular are very strictly controlled. Detailed descriptions of any plant and process used in drug manufacture have to be lodged in documented form with the FDA, wherein every aspect of process description is given. This must include raw material

definition and suppliers, stability data for every step of the process, formulation methods, packaging, labelling, toxicity data and so on. The documentation has to be revised annually and any changes notified. Furthermore plant and process is open to inspection at all times for full audit of procedure. There is one large anomaly within the regulations. The largest volume of material in contact with a drug during manufacture is water, solvents and salts, all of which are exactly defined in terms of their physicochemical characteristics. The next largest is chromatographic media; ambiguously media do not have to be described in the same detail.

The outstanding stability of the synthetic chromatography media provides an excellent opportunity to develop and register Drug Master Files

Figure 10 Model of the Phe-Arg dipeptidyl substrate bound in the active site of porcine pancreatic kallikrein. The illustration shows Asp189 at the bottom of the primary binding pocket as well as the side chains of Tyr99 and Trp215, which form the secondary binding pocket, with the phenyl ring of the Phe residue sandwiched between the hydrophobic side chains of these residues.

(DMFs) with the FDA. DMFs allows companies to use synthesized ligands for very high purity protein pharmaceuticals with total confidence. New Drug Applications (NDA) and Investigational New Drugs (IND) documents incorporating such stable affinity media can now be submitted to the FDA, safe in the knowledge that all appropriate information is on file. The effective guarantee of minimum quality

standards and Good Manufacturing Practice (GMP) is an integral part of a DMF. Few researchers selecting a specific medium consider the long-term implications of stability under depyrogenating conditions, the number of cycles that can be achieved (lifetime in use), its availability in bulk, whether it is manufactured under aseptic conditions and the price when supplied in bulk. If the researcher makes a good initial selection, the research data produced can be utilized in development phases with confidence. 'Fast tracking' is facilitated, with minimum aggravation, maximum efficiency and minimum purification costs.

Figure 11 Comparison of the structures of (A) the Phe-Arg dipeptide, and (B) the 'biomimetic' ligand designed to bind at the active site of the porcine pancreatic kallikrein.

Alternative Affinity Approaches

Aqueous two-phase systems have been extensively applied to bimolecular purifications, by attaching affinity ligands to one of a pair of phase-forming polymers, a method known as *affinity partitioning*. Although a substantial body of research literature is available, few systems appear to have been adopted for commercial purposes. Reactive dyes, with their simple and well-defined coupling chemistries, have generally been favoured as the active ligand. The advantage of affinity partitioning is that the process is less diffusion-controlled, binding capacities

are high and the recovery of bound proteins is easier, created by the process operating with fewer theoretical plates than those generated by chromatography columns. This technique has also been combined with *affinity precipitation*, where a homobifunctional ligand composed of two ligand entities connected by a spacer (for example a bis-dye) is used. However, even in combination this approach suffers from considerable nonspecific binding and relatively low purification factors. A review of this combination suggests that it is more suited to large scale, low purity products. In contrast, perfluorocarbon emulsion chemistry utilizing mixer-settlers may offer more promise. By using a series of mixer-settlers connected in a loop a continuous process has been developed. A ligand (usually a reactive dye) is covalently bonded to a high density perfluorocarbon emulsion and contacted with the crude protein solution. After settling in the first tank the emulsion is pumped to a second settler and washed before passing to the third settler for elution. The emulsion is regenerated in the fourth settler. The supernatants from each settler, still containing some unbound target protein, are normally discarded. Although reasonable recoveries and yields are obtained, significant development is needed for this type of system to become competitive with conventional chromatography column methods.

Another favoured research approach to improving efficiency is to use *expanded beds*. Various techniques have been tried, with the primary objective of eliminating the 'solid bed' effect, where the bed acts as a filter, trapping insolubles and creating significant back-pressure. By partially removing the normal constraints of upper and lower retaining frits, which pack the particles tightly in the bed, the particles can expand, thereby releasing trapped solid impurities. Consequently longer operational cycles and higher flows result. One limitation of the expanded bed system is that adsorption can only be carried out in one stage, resulting in a less efficient process.

Expanded beds are only an intermediate stage towards *fluidized beds*. Several variations of fluidized bed technology have been adopted to evaluate them for affinity processing. One example is the use of perfluorocarbon emulsions in a countercurrent contactor. The affinity perfluorocarbon emulsion is loaded with crude source material into the base of a column in a similar manner to that of an expanded bed. The adsorbent is then removed from the base of the bed and carried forward through four identical contactors where washing, elution and regeneration are carried out successively. This process is claimed to improve significantly removal of target proteins compared to an expanded bed system.

Affinity Membranes

Ultrafiltration membranes are commonly employed as a 'polishing' stage of multistage separation processes for several commercially important proteins. Consequently attaching standard affinity ligands to create affinity membranes has become an actively researched area. The most obvious advantage of a membrane structure is the high rate of transport of the medium through the porous structure by filtration, thus minimizing the normally encountered diffusion limitations of mass transfer. High adsorption rates are achieved, especially if long distance electrostatic interactions are involved in the binding mechanism. However, in contrast to ion exchange membranes, similar high transport effects are not observed when used in the affinity mode, eliminating much of the initial attraction of this form of device. Other theoretically attractive features included: an inherent ability to control pore size across a very wide range, offering an opportunity to increase capacity of a given system; and ability to operate in either batch mode or filtration mode. In both cases experimental data have not confirmed these assumed advantages; a 10-fold change in the pore size resulted in only a two-fold capacity increase and when in filtration mode, although adsorption is fast, severe peak broadening on elution is experienced.

The chemistry relevant to particulate media is identical to that required for membranes, in effect making the systems compatible and allowing an easy technology interchange. The covalent bonding of affinity ligands to the surface of a membrane follows exactly the same chemistry as that applied to particulate media, and the same adsorption/desorption principles apply to both. Consequently the only difference between membrane systems and those of conventional chromatography is the exploitation of the characteristics of the membrane matrix compared with a particulate bed. Although the high mechanical strength of membranes is one major advantage, plus the scale-up is claimed to be very easy by stacking membranes (although scaling affinity columns is also very straightforward), it has been discovered that if the pressure drop across the membrane is too high sealing problems occur; the mobile phase then flows beyond the edges and past the membranes. Furthermore affinity membranes should be capable of use with unclarified extracts, but it has been generally observed that membrane capacity and lifetime are progressively reduced with time of use. Even with clarified broths, membrane fouling regularly occurs. This is almost certainly the reason why affinity membranes have not found favour in large scale processing.

Conclusion

Protein separations can be achieved by a variety of affinity techniques, but separations in the chromatography mode are by far the most widely used. Nature defined an appropriate pathway to highly efficient separation – utilization of the phenomenon of the automatic recognition mechanism existing between a given protein and at least one other. By covalently bonding one of the pair onto an inert matrix a theoretically simple separation process can be devised. Although these immunoaffinity separations are widely practised today, severe limitations exist, not least of which are cost and instability of the affinity medium when in use. As modern design aids have become commonplace, in conjunction with newer techniques such as the development of combinatorial library arrays, it has proved possible to mimic nature and replace immunoaffinity matrices by specifically designed synthetic ligands. These new ligands not only accurately emulate the exquisite precision of the natural protein–protein interaction mechanisms, but also provide the opportunity to manipulate the ligand structures, thus offering far more efficient separations than any previously achieved. For a given protein, from whatever source and at any dilution, it is now possible virtually to guarantee that a highly cost-effective and highly efficient separation process can be developed for eventual commercial use.

Designed ligand processes have already been adopted for several very large biotechnology projects scheduled to manufacture bulk protein pharmaceut-

icals. A mandatory part of any new protein pharmaceutical process is the acceptance by regulatory authorities of the separation process involved. That synthesized affinity ligand separation processes have now been fully accepted by the foremost regulatory authority, the USA's Food and Drug Administration, confirms a worldwide acceptance of the power of ligand design technologies.

Research, Lexington, KY, USA

Copyright © 2000 Academic Press

Introduction

Centrifugation is a mechanical process that utilizes an applied centrifugal force field to separate the components of a mixture according to density and/or particle size. The principles that govern particle behaviour during centrifugation are intuitively comprehensible. This may, in part, explain why centrifugation is seldom a part of post-secondary science curricula despite the broad range of scientific, medical and industrial applications in which this technique

has been employed for well over 100 years. Applications that range from the mundane, industrial-scale dewatering of coal fines to the provision of an invaluable tool for biomedical research.

The first scientific studies conducted by Knight in 1806 reported the differences in orientation of roots and stems of seedlings when placed in a rotating wheel. However, it was not until some 60 years later that centrifuges were first used in industrial applications. The first *continuous* centrifuge, designed in 1878 by the Swedish inventor De Laval to separate cream from milk, opened the door to a broad range of industrial applications. About this same time, the first centrifuges containing small test tubes appeared. These were modest, hand-operated units that attained speeds up to 3000 rpm. The first electrically driven

centrifuges were introduced in 1910, further accelerating centrifuge development. Svedberg's invention of the analytical ultracentrifuge in 1923, operating at 10 000 rpm and equipped with transparent observation windows, marked another milestone in centrifuge technology. In the 1940s, the isolation of the first subcellular components by centrifugal techniques not only served to revolutionize our knowledge of the structure, composition and function of intracellular components, but demonstrated the potential of centrifugal methods for biomedical research. Although temporarily abandoned in 1943 in favour of a gaseous diffusion process, industrial-scale gas centrifuges were rapidly developed during World War II in an effort to enrich or separate uranium isotopes. In 1943, Pickels was the first to employ a sucrose-based density gradient to measure particle sedimentation rates. Density gradient centrifugation was further refined in the 1950s by Brakke, who applied the concept to purification and characterization of viruses, and by Anderson and co-workers at Oak Ridge National Laboratory, who designed a series of zonal centrifuge rotors for separation of subcellular particles and viruses. More recent advances have been characterized by significant improvements in materials and equipment and a broadening range of applications.

Today, centrifuges are routinely used in a variety of disciplines ranging from large-scale commercial applications to laboratory-scale scientific research. The number of centrifuge designs and configurations used in the mineral, petrochemical, chemical, medical, pharmaceutical, municipal/industrial waste, dairy, food, polymer, energy and agricultural industries (to name a few) seem almost as numerous as the applications themselves. An in-depth description of centrifuge designs and applications is, therefore, well beyond the scope of this treatise. Instead, this article will present the reader with an introduction to the theory of centrifugation, an overview of the various types of centrifugal separations, and a description of selected rotor/centrifuge designs and their more common applications.

Theory

Sedimentation by Gravity

A particle suspended in a liquid medium of lesser density tends to sediment downward due to the force of gravity, F_g . Newton showed that an object is accelerated by the gravitational force according to the relation:

$$F_g = mg = m \times 980 \text{ cm s}^{-2} \quad [1]$$

where m is the mass of the object and g is the acceleration due to gravity.

In an idealized case of a free-falling object being accelerated by gravity in a vacuum, the velocity of the object would exhibit a uniform rate of increase. However, for a real-world case of an object falling through air, or more appropriately for our purposes, settling in a liquid medium, there are two forces that oppose the gravitational force; the *buoyancy force*, F_b , and the *frictional force*, F_f .

Buoyancy force The buoyancy force was first noted by Archimedes, who showed that a particle suspended in a fluid experiences an upwards force that is equivalent to the weight of the fluid displaced:

$$F_b = m_M g = V_p \rho_M g \quad [2]$$

where m_M is the mass of the fluid medium displaced, V_p is the volume of the particle (=volume of the displaced fluid), and ρ_M is the density of the displaced fluid.

At pressures up to several bars (1 bar = 10^5 Pa), the buoyancy force in air or other gaseous media can be neglected to a first approximation with respect to the net gravitational acceleration experienced by solids or liquids. However, in a liquid medium, the buoyancy force is substantial. Since the volume of the settling material is equal to the volume of the fluid being displaced, the net gravitational force experienced by the particle is proportional to the difference between the mass of the particle and that of the displaced medium. Thus, assuming gravity sedimentation of a spherical particle with radius r and volume of $\frac{4}{3}\pi r^3$, eqn [1] can be rewritten to show the net gravitational effect, $F_{g\text{-net}}$:

$$F_{g\text{-net}} = \frac{4}{3}\pi r^3 (\rho_p - \rho_M) g = \frac{4}{3}\pi r^3 (\rho_p - \rho_M) \times 980 \text{ cm s}^{-2} \quad [3]$$

where ρ_M is the density of the medium (g cm^{-3}); ρ_p is the particle density (g cm^{-3}); and r is the particle radius (cm).

For those instances in which the medium density is greater than the density of the material in suspension, the net effect is negative, that is, particles would experience a net upward force in such instances and would tend to rise through the medium.

Frictional force, F_f In addition to the buoyancy force, the movement of a particle through a fluid medium is hindered by the viscosity of the medium, η , as described for a spherical particle by Stokes' equation:

$$F_f = 6\pi\eta r(dx/dt) \quad [4]$$

where η is the viscosity of the medium in poise, P ($\text{g cm}^{-1} \text{s}^{-1}$); r is the radius of the particle (cm); and (dx/dt) is the velocity of the moving particle (cm s^{-1}).

Eqn [4] shows that the frictional force is proportional to the particle velocity and its diameter. At low velocities and pressures, the frictional force is again negligible in a gas. However, at higher velocities, even in gases, this force becomes substantial, combining with the buoyancy force eventually to exactly oppose the gravitational force, resulting in no further acceleration of the particle. This condition is known as the limiting or *terminal velocity*. Mathematically, the conditions for attaining terminal velocity are met when:

$$F_g = F_b + F_f \quad [5]$$

The above discussion would imply that with sufficient time completely pure phases can be obtained by gravity sedimentation alone. While this may be true for the sedimentation of large particles in a medium with a significantly higher or lower density than the particle, this is not the case for smaller particles, which are impacted by diffusional forces that ultimately limit the separation efficiency as well as to other nonideality effects (see below).

Diffusion Random Brownian motion results in the net movement of solute or suspended particles from regions of higher concentration to regions of lower concentration, a process called diffusion. Thus, diffusion works in opposition to centrifugal sedimentation, which tends to concentrate particles. The rate of diffusion of a particle is given by Fick's law:

$$dP/dt = -DA(dP/dx) \quad [6]$$

where D is the diffusion coefficient which varies for each solute and particle; A is the cross-sectional area through which the particle diffuses; and dP/dx is the particle concentration gradient.

The precise impact of diffusion can be difficult and cumbersome to calculate for complex systems. It is often sufficient to keep in mind that the rate of diffusion is generally more pronounced for smaller particles than for larger ones, it increases with temperature, and its effects are lessened by higher centrifugal forces.

Aside from theoretical considerations, in a more practical sense, the time required for the settling of small to medium size particles in a gravitational field is often prohibitive. Additional obstacles to obtaining pure phases during gravity settling can also arise from

attractive forces between the particles being separated and/or the medium in which they are suspended. Often, gravitational force alone is insufficient to provide the minimum force necessary to disrupt such attractions. The use of centrifugal settling addresses the shortcomings of gravity settling by shortening the time required for sample recovery at a given purity, providing a greater force for disrupting particle/particle or particle/media interactions and, within limits, lessening the detrimental effects of diffusion.

Sedimentation in a Centrifugal Field

A particle moving in a circular path continuously experiences a *centrifugal force*, F_c . This force acts in the plane described by the circular path and is directed away from the axis of rotation. The centrifugal force may be expressed as:

$$F_c = ma = m\omega^2x \quad [7]$$

where m is the particle mass (g); a is the acceleration (cm s^{-2}); ω is the angular velocity ($\text{radians s}^{-1} = 2\pi \text{rpm}/60$); and x is the radial distance from the axis of rotation to the particle (cm).

Thus, centrifugal force is proportional to the square of the angular velocity and to the radial distance from the axis of rotation. The force generated during centrifugation can be compared to the gravitational force by the *relative centrifugal force*, RCF, often referred to as the *g* force:

$$\text{RCF} = F_c/F_g = (m\omega^2x)/(mg) = (\omega^2x)/g \quad [8]$$

Converting ω to rpm and substituting values for the acceleration due to gravity, eqn [8] can be rewritten in a more convenient form as:

$$\text{RCF} = 1.119 \times 10^{-5}(\text{rpm})^2x \quad [9]$$

While RCF is a ratio, and therefore unitless, it is frequently expressed in units of *g* to indicate the number of times that the force of the applied centrifugal field is greater than the force of gravity.

The forces acting on a particle suspended in a liquid medium in a centrifugal field are illustrated in **Figure 1**. Within the centrifugal plane, the centrifugal force acts to move particles away from the axis of rotation, while the buoyancy and frictional forces oppose this movement. The effect of the Earth's gravity can generally be regarded as negligible. Analogous to the conditions for attaining terminal velocity in a gravitational field (eqn [5]), the particle will reach a limiting or terminal velocity in a centrifugal field when the sum of the frictional and buoyancy

Figure 1 Forces acting on a particle in a centrifugal field: F_b , buoyancy; F_f , frictional; F_c , centrifugal; and F_g , gravitational.

forces equals the centrifugal force:

$$F_c = F_b + F_f \quad [10]$$

Substituting eqns [2], [4] and [7] into eqn [10] gives:

$$m\omega^2 x = V_p \rho_M \omega^2 x + 6\pi\eta r(dx/dt) \quad [11]$$

Assuming a spherical particle and substituting $\frac{4}{3}\pi r^3$ for volume gives:

$$(\frac{4}{3}\pi r^3)\rho_P \omega^2 x = (\frac{4}{3}\pi r^3)\rho_M \omega^2 x + 6\pi\eta r(dx/dt) \quad [12]$$

Then solving for dx/dt :

$$dx/dt = [2r^2(\rho_P - \rho_M)\omega^2 x]/9\eta \quad [13]$$

Eqn [13] is more commonly expressed in terms of particle velocity, v , and particle diameter, d :

$$v = (d^2(\rho_P - \rho_M)\omega^2 x)/18\eta \quad [14]$$

Eqn [14] may be integrated to determine the time required for a particle to traverse a radial distance from x_0 to x_1 :

$$t = [18\eta/(d^2(\rho_P - \rho_M)\omega^2)] \ln(x_1/x_0) \quad [15]$$

where x_0 is the initial position of the particle and x_1 is the final position of the particle.

While modifications can be made to eqns [13]–[15] to account for specific rotor design, liquid–liquid, density-gradient separations, etc., these equations describe the relative impact of the more significant para-

eters that govern settling velocity. They show that the sedimentation rate (i.e. limiting velocity) of a particle in a centrifugal field:

- increases as the square of the particle diameter and rotor speed, i.e. doubling the speed or particle diameter will lessen the run time by a factor of four;
- increases proportionally with distance from the axis or rotation; and
- is inversely related to the viscosity of the carrier medium.

These are the fundamental premises that a practitioner must know in order to develop a rational approach to centrifugal separation.

Sedimentation Coefficient

Since the terms r , ρ_P , ρ_M and η as given in eqns [13]–[15] are constant for a given particle in a homogeneous medium, the sedimentation rate, dx/dt , is proportional to $\omega^2 x$. This proportionality is often expressed in terms of the sedimentation coefficient, S , which is simply a measure of the sedimentation velocity per unit of centrifugal force. For a given set of run conditions, the sedimentation coefficient, S_r , may be calculated as:

$$S_r = (dx/dt)/(\omega^2 x) = 2r^2(\rho_P - \rho_M)/9\eta \quad [16]$$

The sedimentation coefficient, S , has the dimensions of seconds and is expressed in Svedberg units equal to 10^{-13} s. Its value is dependent on the particle being separated, the centrifugal force and the properties of the sedimentation medium. While adequate for a given set of run conditions, it is sometimes useful to compare sedimentation coefficients obtained under differing conditions and/or sedimentation media by reference to the behaviour of the particle in water at 20°C, $S_{20,w}$:

$$S_{20,w} = S_{T,M}\eta_{T,M}(\rho_P - \rho_{20,w})/\eta_{20,w}(\rho_P - \rho_{T,M}) \quad [17]$$

where the subscripts T and M denote the experimental temperature and medium, respectively.

Rotor Efficiency

The time required for a particle to traverse a rotor is known as the pelleting efficiency or *k-factor*. The *k*- or clearing factor, which is calculated at the maximum rated rotor speed, is a function of rotor design and is a constant for a given rotor. *k*-Factors provide a convenient means of determining the minimum residence time required to pellet a particle in a given

rotor and are useful for comparing sedimentation times for different rotors. The k -factor is derived from the equation:

$$k = \ln(r_{\max} - r_{\min}) \times 10^{13} / (3600\omega^2) \\ = 2.53 \times 10^{11} \times \ln(r_{\max} - r_{\min}) / \text{rpm}^2 \quad [18]$$

where r_{\max} and r_{\min} are the maximum and minimum distances from the centrifugal axis, respectively.

Eqn [18] shows that the lower the k -factor, the shorter the time required for pelleting. If the sedimentation coefficient of a particle is known, then the rotor k -factor can also be calculated from the relation:

$$k = TS \quad [19]$$

where T is the time in hours required for pelleting and S is the sedimentation coefficient in Svedberg units.

When k is known (normally provided by the manufacturer), then eqn [19] may be rearranged to calculate the minimum run time required for particle pelleting.

For runs conducted at less than the maximum rated rotor speed, the k -factor may be adjusted according to:

$$k_{\text{adj}} = k(\text{rpm}_{\max} / \text{rpm}_{\text{act}})^2 \quad [20]$$

where rpm_{\max} and rpm_{act} are the maximum rated rotor speed and actual run speed, respectively.

k -Factors are also useful when switching from a rotor with a known pelleting time, t_1 , to a second rotor of differing geometry by solving for t_2 in the relation:

$$t_1/t_2 = k_1/k_2 \quad [21]$$

where t_1 , t_2 , k_1 and k_2 are the pelleting times and k -factors for rotors 1 and 2, respectively.

Deviation from Ideal Behaviour

Eqns [13] and [14] showed the relative impact on settling velocity of the more important and controllable experimental parameters. However, there are other effects that are more difficult to characterize and which can result in significant deviations from the settling velocities predicted by these equations. The most common of these effects occurs when the particles are nonspherical, as these equations are derived from Stokes' equation assuming spherical particles. For nonspherical particles, eqns [13] and [14] may be modified with a correction

term, θ . In Stokes' equation, the term $6\pi\eta r$ describes the *frictional coefficient*, f_0 , for a spherical particle. The correction term, θ , is calculated as the ratio of the frictional resistance, f , encountered by a particle of nonspherical geometry to that encountered by a sphere of the same volume, or:

$$\theta = f/f_0 = f/6\pi\eta r \quad [22]$$

The equation describing the terminal velocity for nonspherical particles in a centrifugal field may be rewritten as:

$$dx/dt = [d_e^2(\rho_p - \rho_m)\omega^2 x] / 18\eta\theta \quad [23]$$

where d_e is the diameter of a sphere whose volume equals that of the sedimenting particle ($d_e/2$ is the Stokes radius).

The net result of this modification is that nonspherical particles are predicted to sediment more slowly, which is a more accurate depiction of their real-world behaviour.

In addition to deviations from spherical-particle geometry, there are other effects that can lead to departure from predicted behaviour (nonideality) during sedimentation. For example, many biological particles interact with the medium via hydration, the extreme case being for those particles with osmotic properties, which can result in drastic changes in particle density and, in turn, sedimentation coefficients. Interparticle attractions, e.g. charge or hydrophobic effects, may increase the effective viscosity of the medium. In more severe cases such attractions can lead to poor separations where the centrifugal energy is insufficient to disrupt the attractions between particles that are targeted for separation. This latter effect is aggravated by the fact that the larger or denser particle will lead as the particle pair migrates toward the rotor wall while the smaller or lighter attached particle follows in its wake, and therefore experiences less frictional drag. Particles may also concentrate locally to increase the effective medium density, or form aggregates that yield complicated sedimentation patterns. Because of such deviations from ideal behaviour, equivalent sedimentation coefficients, S^* , defined as the sedimentation coefficient of an ideal spherical particle, are often reported for a given set of experimental conditions.

Filtration

A mathematical description of liquid drainage from a packed bed by centrifugal forces is essentially the same as that used to describe more conventional gravity or differential-pressure filtration, the primary differences being that the centrifugal force

or the pressure generated by the centrifugal force is substituted for the gravitational or differential-pressure terms. As filtration is an extensively characterized field of study, a description of which is beyond the scope of this article, it is recommended that the reader refer to the literature for an in-depth mathematical discussion of both conventional and centrifugal filtration. However, a brief summary of some of the more important parameters that govern flow velocity and pressure drop during centrifugal filtration follow. A simple basket centrifuge is shown schematically in Figure 2. Assuming a constant height of liquid within the basket, the velocity of the filtrate, u , through a given cake thickness, dl , is given by the relation:

$$u = [1/(2\pi r' H)] dV/dt = [1/a\mu](-dP'/dl) \quad [24]$$

where H is the basket height or length ($2\pi r' H$ is the cross-sectional area of the filter); r' is the distance from the axis of rotation to the inner cake surface; dV/dt is the volume of filtrate passing in time dt ; a is the specific resistance of the cake; μ is the viscosity of the filtrate; dP' is the pressure drop across a given thickness of filter cake; and dl is a given cake thickness.

The velocity of the filtrate through the cake and underlying filter is thus proportional to the volume of filtrate flow or the pressure differential across the filter cake, and inversely related to the surface area of the filter, filtrate viscosity and cake resistance. Eqn [24] may be rearranged and integrated to determine the total pressure drop across the cake at time t :

$$-\Delta P' = (a\mu/2\pi H) dV/dt \ln(r/r') \quad [25]$$

where r is the distance from the axis of rotation to the outer cake surface.

Figure 2 Basket filtration centrifuge.

If the resistance of the filter is negligible, $\Delta P'$ is equivalent to the centrifugal pressure. A parameter that is widely used to characterize the performance of filtration equipment is the drainage number:

$$\text{Drainage number} = \bar{d}(G)^{1/2}/\mu \quad [26]$$

where \bar{d} is the mean particle diameter (μm); G is the centrifugal force ($=\omega^2 r/g$), where r is the largest radius for a variable radius screen; and μ is the filtrate viscosity ($\text{m}^2 \text{s}^{-1}$). Higher drainage numbers correspond to more rapid drainage.

Types of Separation

One approach to classify centrifugal separations is according to the phase of the medium and the phase of the material to be purified, e.g. gas-gas, liquid-liquid or liquid-solid. Centrifugal separations of gas-phase materials are conducted in continuous mode only, while liquid-liquid and liquid-solid may be conducted in batch, semi-batch, or continuous modes. Gas-phase separations are very important in certain applications, particularly uranium isotope enrichment, but are highly specialized and not widely used. For space considerations, gas-phase separations are omitted from this discussion. Likewise, while liquid-liquid and even liquid-liquid-solid separations are common, discussion of the separation of immiscible liquids is, for the most part, limited to the discussion of centrifuge types in subsequent sections. Suffice it to say that the principles and approaches discussed in relation to liquid-solid separations generally apply to liquid-liquid separations. That is, small droplets of a liquid dispersed in a second, immiscible liquid will behave like solid particles settling through a liquid medium until the droplets sediment and coalesce, after which the methods to remove the separated liquids from the centrifuge usually differ from those used for solids removal.

Centrifugal separations may also be classified according to the method by which purified fractions are recovered. Three modes are used: (1) batch mode, in which the total sample to be separated is processed and then recovered at the conclusion of the run by decanting the supernatant and scraping the pellet from the rotor wall; (2) semi-batch mode, in which the sample mix is continuously fed to a spinning rotor as the supernatant is continuously discharged and the pellet is permitted to accumulate for post-run removal; and (3) continuous mode, in which the sample mixture is fed continuously, the supernatant is continuously discharged, and denser liquid or solid materials are either intermittently or continuously discharged while the run is in progress.

The types of separation to be discussed focus on the separation of solids from liquid media using any of the recovery modes described above. Discussion of simpler batch-mode operation is emphasized for simplicity. Three primary types of centrifugal separations are discussed: differential sedimentation, density gradient and filtration, with density gradient being further divided into rate-zonal and isopycnic (in isopycnic separations, particles sediment until they attain a position in the gradient at which the medium density is equal to their own).

Differential Sedimentation

As previously shown by the equations describing sedimentation (eqns [13] and [14]), larger and/or denser particles will sediment more rapidly in a centrifugal force field and will thus pellet onto the outer wall of the rotor faster than smaller or lighter particles. Most applications are based on this difference in behaviour, referred to as differential sedimentation or *pelleting*. In a simple batch-mode pelleting separation, a sample mixture called the homogenate (immiscible liquids or solid suspensions) is placed into a centrifuge container or rotor, and separated into two fractions as depicted in Figure 3. The unsedimented material is termed the *supernatant* and the sedimented material is the *pellet*. This approach works well when the objective is to pellet all the solid particles or to clarify the liquid. Such separations are also commonly used in the laboratory for 'quick and dirty' separations or where the objective is to enrich or clarify materials for subsequent analysis.

Obtaining high purity separations by differential sedimentation is more difficult. With respect

to separating particles of similar density according to size (classification), an approximate order of magnitude difference in mass between the particles is needed for differential sedimentation to be effective. The main disadvantage of separating a homogenate in batch mode is that the centrifugal field required to pellet the larger or denser particles that are initially nearer the axis of rotation is capable of pelleting smaller or lighter particles initially closer to the outer wall (Figure 3). Product purity or recovery may be improved by either recentrifuging the supernatant to obtain more pellet, or by resuspending the pellet and recentrifuging to obtain higher purity. When purity is the primary concern, this approach can still be used as a preparatory step to provide an enriched fraction for subsequent purification. However, a more efficient one-step approach is to layer the sample mixture on top of the preloaded medium. Stopping the run before the lighter or smaller contaminant particles reach the rotor wall allows them to be decanted with the supernatant. An alternative is to use a continuous-feed rotor in which the sample mixture is introduced near the axis of rotation and the supernatant, containing the smaller or lighter unsedimented particles, is continuously discharged. A more efficient approach is to layer or feed the sample to the top of a preloaded density gradient (see below).

Density Gradient Centrifugation (DGC)

DGC, developed in the 1950s, also relies on differential sedimentation behaviour to separate sample components, but compensates for some of the disadvantages of homogeneous media and also allows for the simultaneous separation of multicomponent mixtures. This is accomplished by the use of a density gradient, i.e. a liquid medium that increases in density from the layers nearest the axis of rotation to those farthest away. As will be discussed, this is achieved through variation in the concentration of an aqueous solute, or other gradient material, across the rotor. With minimal precautions, density gradients are surprisingly stable for extended periods, even with the rotor stopped. DGC separations are more extensively used for smaller-scale research applications in contrast to large-scale pelleting separations that are more common to industrial applications. DGC may be conducted as either rate or isopycnic separations.

Rate-zonal separations This technique, also called classification, is used to separate particles of similar density according to size. For batch separations, the sample mixture is layered on top of a preloaded medium, as shown in Figure 4. During a rate-zonal

Figure 3 Differential sedimentation or pelleting. (Courtesy of Beckman Instruments, Inc.)

Figure 4 Rate-zonal separation in a swinging-bucket rotor. (Courtesy of Beckman Instruments, Inc.)

separation, larger particles sediment more rapidly, just as in a pelleting run. Also similar to a pelleting run, the maximum medium density is lower than the density of the particles being processed. However, unlike pelleting runs, the run must be stopped before particles reach the bottom of the tube or rotor wall, otherwise all sample components will simply sediment to the pellet.

Rate or *setting velocity* separations may be conducted with a homogeneous medium in batch or semi-batch mode. However, the use of density-gradient media offers several advantages. The steep gradient beneath the layer of sample suppresses premature sedimentation as well as convection currents in the liquid column, both of which lower the separation efficiency. In addition, the continuous increase in density, often accompanied by an increase in viscosity across the rotor, serves to slow the faster-moving particles and provide better resolution in the sample component *bands*. Increasing-viscosity gradients also lessen diffusional effects, though this advantage may be offset by an increase in the required run time. Rate-zonal separations are well suited for mixtures of particles of similar density that exhibit two or more well-defined modes of size distribution. However, owing to the additional steps and equipment required for DGC as opposed to pelleting, DGC separations are more commonly used to separate particle mixtures based on a parameter other than size, e.g. density.

Isopycnic separations These separations, which are based on differences in particle densities, are

conducted in a density gradient. The density range of the gradient often spans the full range of particle densities so that particles never reach the rotor wall, regardless of run time. Instead, particles move through the gradient until they reach a position in which the medium density is the same as their own (Figure 5). As governed by the settling velocity equations (eqns [13] and [14]), particles introduced to the top of a performed gradient sediment relatively quickly at first, with movement slowing as the difference in density between particles and gradient lessens and essentially stopping once the particles reach a position in the rotor where the density of the medium is equal to their own. Particles remain in this terminal position even after the rotor is stopped; this allows them to be recovered as density fractions. Differences in particle size only affect their rate of movement, though this may ultimately dictate the required run time. When the range of particle densities exceeds the range of the density gradient, then a mixture of pelleting and isopycnic separations will occur as some particles fully traverse the rotor and pellet while others attain their isopycnic position and remain suspended. While most density gradients are formed by the loading of solutions of successively higher density to the rotor, it is possible to form such gradients *in situ* from a homogeneous solution at high

Figure 5 Isopycnic separation with a self-generating gradient. (Courtesy of Beckman Instruments, Inc.)

centrifugal speeds. This is achieved by routing the solutions to the rotor wall through veins in the central core. When such *self-generating* gradients are used, it is not necessary that the sample be layered on top of the solution but instead it may be mixed with the medium prior to loading (Figure 5). While self-generating gradients offer greater simplicity, they often require a significant increase in run time. For instance, though the advent of vertical tubes, faster centrifugal speeds, and overspeeding techniques have reduced run times to about one-third of those required only a few years ago, runs of 3 to 12 h are still typical for DNA banding experiments.

Isopycnic separation is a more powerful separation tool than rate-zonal separation in the sense that a generally greater number of particle types can be resolved. However, rate runs may still be preferred for separating large and/or fragile particles, since shorter run times and lower centrifugal forces are used. Run duration is crucial for a rate separation, whereas isopycnic runs simply require a minimum time for the particles to reach a stationary state. It is sometimes useful to conduct a two-dimensional separation in which, for instance, a rate-zonal run generates fractions of particles with similar *S* values that are further fractionated according to density in an isopycnic separation. The reverse process can also be performed to yield particles of similar density but different particle size distributions.

Gradient materials The selection of an appropriate gradient material is an important consideration as the gradient properties must be compatible with the separation objectives. The desired properties of an ideal gradient material, as set forth by Griffith and by Ridge, are summarized below.

The ideal gradient material should:

- span a density range sufficient to permit separation of the particles of interest without overstressing the rotor;

- be stable in solution;
- be inert towards the fractionated materials, including biological activity;
- exert the minimum osmotic effect, ionic strength and pH;
- be removable from the product;
- be readily available and either inexpensive or easily recyclable;
- be sterilizable.

It should not:

- generate a prohibitively high viscosity;
- interfere with the assay technique (e.g. absorb UV or visible light);
- be corrosive; or
- generate flammable or toxic aerosols.

From this list of properties, it is apparent that no single ideal gradient material exists, as each separation problem imposes its own set of requirements. Rather, selection can only be made after a careful evaluation of the gradient properties with respect to the requirements imposed by the separation to be conducted. The list of materials that have been used for gradient formation is extensive with examples of the more commonly used materials along with selected properties listed in **Table 1**.

With respect to biological inertness and low viscosity, the ideal aqueous gradient material is deuterium oxide (D_2O). However, D_2O is expensive and has a relatively low maximum density (1.11 g cm^{-3}).

Sucrose was used in the pioneering density-gradient work of Brakke and, due to its low cost, transparency, ready availability and nontoxic nature, is still the most widely used. Densities to 1.33 g cm^{-3} can be achieved, which is sufficient for separating most cells and intracellular organelles. However, sucrose solutions are not completely physiologically inactive and often contain UV-absorbing components. Mannitol and sorbitol can be used as substitutes to

Table 1 Physical properties of gradient materials in aqueous solutions at 20°C (from Sheeler, 1981)

Gradient material	Tradename	Maximum solution concentration			20% w/w solution	
		Concentration (% w/w)	Density (g cm^{-3})	Viscosity (cP)	Density (g cm^{-3})	Viscosity (cP)
Sucrose		65	1.33	182	1.08	2
Sucrose polymer	Ficoll	43	1.17	600	1.07	27
Colloidal silica	Ludox-SM	–	1.40	–	1.13	2
Colloidal silica	Percoll	23	1.13	10	1.11	8
Metrizamide		56	1.44	58	1.12	2
CsCl		65	1.91	1.3	1.17	0.9
Polytungstate salt	LST	85	2.89	14	1.20	–
Polytungstate salt	SPT	85	2.89	26	1.20	2

compensate for these deficiencies, but use of these sugars has disadvantages including higher viscosity and lower maximum densities. Polysaccharides also have a low osmotic pressure, but again are more viscous than sucrose solutions of equal density and may induce aggregation of the suspended sample via charge interactions.

Silica sols (e.g. Ludox™ and Percoll™), also called colloidal silica, are prepared from small silica particles in mildly alkaline solution. They provide low viscosities and osmotic pressures, even at high densities, and are transparent and inexpensive. Silica sols provide densities to 1.40 g cm^{-3} . Their disadvantages include a tendency to gel at $\text{pH} < 7$ and problems in complete removal from the sample. Percoll™, prepared by coating the silica particles with a polymer, eliminates the gelling problem and provides low viscosity, low osmotic pressure solutions, greater stability at low pH, and densities to 1.21 g cm^{-3} . However, this material is relatively expensive and removal from the sample can be a problem.

Salts are used to generate very high density aqueous solutions. Cesium chloride is by far the most widely used of this class. CsCl solutions can reach densities of $\sim 1.9 \text{ g cm}^{-3}$ at saturation while providing a very low viscosity at lower concentrations. Although expensive, CsCl can be readily recovered and purified. CsCl solutions also have a high osmotic pressure and are corrosive, though the titanium rotors generally used with this solute are relatively resistant. CsCl gradients are commonly used in applications ranging from the separation of viruses and dense cellular macromolecules such as DNA, to geological polymers found in coal or oil shale. Other salts that have been used to produce high density gradients include sodium bromide, sodium iodide, cesium bromide, cesium sulfate, cesium formate, cesium trifluoroacetate, rubidium bromide and rubidium chloride. Though expensive, tungstate polymers such as sodium polytungstate (SPT) and lithium heteropolytungstate (LST) have recently been used to generate aqueous gradients well over 2.5 g cm^{-3} . Applications

for these materials include the separation of graphitic carbon and mineral components from fly ash. When using such high density salt solutions, the user should be aware that at high concentration, salts may precipitate on the rotor wall, thereby generating high point densities and the potential for catastrophic rotor failure.

For nonaqueous gradients, organic liquids such as toluene, methanol or kerosene may be blended to attain gradient densities lower than that of water (1.0 g cm^{-3}). Of these, methanol presents an additional advantage of being water-soluble, thereby allowing gradients to be formed from a combination of the two. On the other end of the density scale, halogenated liquids such as diodomethane, bromoform and tetrabromoethane can be used to prepare very dense solutions over 2.8 g cm^{-3} . Problems associated with flammability, toxicity and attack of transfer lines and seals must be considered when using these materials.

Gradient formation and shape Gradient shape refers to the density profile across the tube or rotor as a function of gradient volume (Figure 6). Its choice is important as it governs the sedimentation rate in both rate and isopycnic experiments as well as the terminal position in isopycnic runs.

Gradients may be classified as *step* or *continuous*, as defined by the method of preparation. Step (discontinuous) gradients are prepared by the stepwise addition of solutions of successively higher density to the outer wall or bottom of the rotor. Steps gradients have the advantages that they may be formed without the need for a gradient generator. These gradients may also be readily *tailored* to provide larger volumes of separation media in the ranges that correspond to the density profile of the particles to be separated, thereby, permitting higher sample loadings. For continuous gradients, including the self-generating variety, the medium density varies in a continuous manner across the rotor or tube. Continuous gradients are classified as linear, exponential or isokinetic.

Figure 6 Gradient shapes: (A) linear; (B) exponential; and (C) isokinetic.

In a linear gradient, density increases linearly with distance from the axis of rotation (Figure 6A), and for cylindrical swing-out rotors, with increasing gradient volume as well. In an exponential gradient, the density increases or decreases exponentially across the rotor, producing convex or concave shapes, respectively, when plotted as a function of radial distance (Figure 6B). Isokinetic gradients are designed to produce a uniform sedimentation velocity throughout the gradient by counterbalancing the increase in centrifugal force particles experience as they traverse the gradient with an increase in the density and viscosity of the medium. Such gradients are often used in analytical rotors to study sedimentation behaviour. Simple linear sucrose gradients loaded in a swinging rotor provide a near isokinetic gradient.

Various methods are used to form gradients. The simplest approach is to form the gradient *in situ*, i.e. self-generating, by mixing the sample with a single-density medium prior to loading, then forming the gradient at high centrifugal speeds. While this is the simplest approach, higher speeds and longer run times are often required. Step gradients are also easily formed by simply pumping targeted volumes of successively denser solutions to the rotor wall. Inexpensive peristaltic pumps provide the simplest means of loading step gradients. The simplest liner-gradient generators consist of two equivalent cross-section cylinders that contain an initial and a limiting solution, respectively. The chambers are interconnected at the base with liquid from the limiting solution being drawn into and mixed with the initial solution as material from the initial-solution chamber is loaded. Exponential gradient generators are similar except that the cross-sectional area of one of the chambers changes in a predetermined manner as the chambers are depleted, thereby changing the relative volume contributed from the two chambers with time. More sophisticated gradient pumps are available including mechanical pumps that use cams to mix variable amounts of low and a high density solution prior to loading or programmable pumps, e.g. a liquid chromatograph pump, to generate the targeted gradient curve shape.

Several approaches are used to analyse and/or fractionate the rotor effluent. The simplest is to split the gradient into fractions according to volume, then subsequently analyse each fraction by chemical (density, absorbance, refractive index, fluorescence) or scintillation methods. However, this approach may be somewhat limited in resolution if the collected fractions are large, and thus represent a wider range in density. An alternative approach is to route the effluent through one or more in-line, low volume flow cells to monitor the gradient properties. Auto-

mated fractionators that select cut points and automatically switch collection vessels rely on such in-line detectors.

Analytical Centrifugation

This is the only type of centrifugal separation in which the primary objective is not to purify or de-water one or more of the feed components. Rather, this method is used to monitor particle sedimentation behaviour. Analytical centrifugation is used to characterize particle properties such as molecular weight, diffusion and sedimentation coefficients, buoyancy density, etc. The critical component in this technique is the addition of a transparent window, e.g. quartz or sapphire, to the centrifuge rotor to permit *in situ* optical measurements. Sample movement is typically monitored by UV absorption or refractive index during high speed separations in ultracentrifuges. Experiments are conducted in batch mode using very small sample volumes, as low as 5 μL for some rotors. Two classes of experiments are conducted in an analytical ultracentrifugation – sedimentation velocity and sedimentation equilibrium – analogous to rate and isopycnic experiments in preparative ultracentrifugation. Of these, sedimentation velocity is the more common. Analytical centrifugation is less common today than in the 1950s when this was the principal method for molecular weight determinations (1–10 kDa). However, the method is still used, primarily in biological applications, for studying phenomena such as interactions between macromolecules and ligand-induced binding events. More recently, this technique has experienced somewhat of a renaissance in drug discovery applications.

Continuous Centrifugation

These separations are similar to those previously discussed in the sense that separations are based on size or density differences. However, unlike batch-mode separation, in continuous centrifugation the sample mixture is introduced continuously to a spinning rotor as the supernatant stream continuously exits. For pelleting separations, the denser product may either accumulate on the rotor wall from where it is recovered after the rotor capacity is reached (semi-batch) or continuously discharged as the rotor spins (continuous mode). Continuous-feed centrifuges may be used for rate, pelleting, filtration, or isopycnic banding separations. They are best suited for applications in which large volumes of sample must be processed, the stream to be recovered is at low concentration, the particle sedimentation coefficient is high (less than about 50 S), or long acceleration/deceleration times are required.

The parameters of primary concern for continuous separations are centrifugal force and flow rate. These parameters must be carefully controlled to provide sufficient time for solid or denser liquids to sediment before being carried out with the supernatant, but not so long as effectively to under utilize the throughput capacity of the rotor. The parameters controlling particle sedimentation are the same in continuous-flow as in batch-mode separations. Therefore, the maximum flow rate that can be utilized in a specific rotor at a given speed may be estimated by using eqn [15] to determine the time required for a given particle to traverse the radial distance from the rotor exit, r_e , and to the outer rotor wall, r_{\max} . With information on liquid volume within the rotor and assuming laminar flow of liquid from the entry to the exit port(s), the flow rate can then be adjusted to provide this minimum residence time. The calculation of the minimum residence time is simpler if the rotor k -factor and the particle sedimentation coefficient are known, in which case the minimum residence time required for pelleting can be calculated from eqn [18] (i.e. $T = k/S$, where T is in hours).

Continuous centrifugation is used extensively in industrial applications, where large sample throughput and recovery is more common. However, laboratory-scale continuous-feed applications are also common, particularly in semi-batch mode where the component to be isolated is present at low concentrations. Owing to the variety of continuous-flow configurations that are available, further discussion of this approach is to be found in the section on centrifugal equipment below.

Filtration

Filtration is a mechanical means of separating solids from a liquid suspension via a porous medium or screen that permits the liquid to pass while retaining the solids. Similar to conventional filtration, achieved via a differential pressure across a filter, centrifugal filtration is driven by the pressure exerted by a liquid medium within a centrifugal force field. Opposing the centrifugal pressure is the combined resistance of the porous medium and filter cake. Centrifugal filters are commonly used to remove or recover coarse and crystalline solids from a fluid slurry, often followed by a rinse cycle to purify the solids and remove the residual mother liquor. In this technique, a sample slurry is fed to the rotor with the centrifugal pressure forcing the carrier liquid through a cylindrical screen or other permeable medium positioned around the outer wall to retain the solids or *filter cake*. The filter cake may be dried by shutting off the slurry feed and spinning the solids to attain resid-

ual moisture contents lower than generally provided by filter presses or vacuum filters. Most centrifugal filtration applications are typically conducted in continuous or semi-batch mode in which the liquids passing the filter are continuously discharged and the filter cake is continuously discharged or recovered post run. Perhaps the most widely used example of centrifugal filtration is the spin cycle in domestic washing machines.

Centrifugal filtration is a complex process that is dependent on a number of parameters including liquid viscosity, cake thickness, centrifugal force, screen area and, importantly, the size and packing characteristics of the particles themselves. Centrifugal filtration may be conducted in batch, semi-batch or continuous mode. While traditional industrial applications commonly use centrifugal filtration to recover solid materials with reduced moisture contents, many laboratory-scale spin filters, particularly in a test-tube configuration, are available. This technique is generally not amenable to broad generalizations and is, therefore, best approached on a case-by-case basis.

Centrifugal Equipment

Centrifuges and rotors are commercially available in literally hundreds of shapes, sizes and configurations. They range from small laboratory-scale units equipped with capillary tubes, operating at speeds in excess of 100 000 rpm or forces approaching 1 000 000 g to large industrial decanters that may continuously process up to 300 000 L h⁻¹. The primary rotor or centrifuge selection criteria must centre on the objective for conducting the separation. Parameters such as batch versus continuous; required centrifugal force and purity; throughput; the number of components to be recovered; sample toxicity/corrosiveness; time; cost; available space; noise tolerances, and so forth must be considered when selecting the appropriate centrifuge/rotor for a given application.

Early rotors were often manufactured of steel or brass, but are now more commonly constructed of aluminium and titanium. Newer carbon composites are also gaining acceptance, with plastics commonly used for small-scale applications and stainless steel for industrial-scale units. Though somewhat more expensive, titanium is particularly suitable as it has both a higher strength-to-density ratio and a high resistance to corrosion and erosion. Selected properties for steel, aluminium and titanium are shown in Table 2.

Centrifuge bottles and tubes are also constructed from a variety of materials. Early tubes were usually glass or stainless steel, but these have largely been replaced by plastics, e.g. polycarbonate, nylon,

Table 2 Strength data for commonly used rotor construction materials (from Sheeler, 1981)

Material	Density ($g\ cm^{-3}$)	Ultimate strength ($g\ cm^{-3}$)	Strength: density ratio
Aluminium	2.79	2159	774
Titanium	4.84	6088	1258
Steel	7.99	7915	991

cellulose nitrate and cellulose acetate, etc. Polycarbonate is one of the more popular materials owing to its transparency and strength. The choice of material is generally dictated by the properties of the particles to be fractionated and, in high speed separations, by the maximum rated g force.

An exhaustive discussion of the many equipment options along with their advantages and disadvantages is beyond the scope of this article. Rather, a brief overview is offered of the more common centrifuge designs together with typical applications. Much of the discussion will assume batch operation, though in most cases rotors are available or may be adapted for batch, semi-batch or continuous-mode operation. However, since continuous-mode centrifuges are so widely used in industrial applications and their analogues are often unavailable in laboratory-scale units, a section describing the more common or innovative continuous-flow configurations is included.

Bottle Centrifuges

The most common laboratory centrifuge is the bottle centrifuge. Bottle centrifuges consist of a motor-driven vertical spindle to which a horizontal rotor, machined with an even number of sample positions (2–36), is attached. The harness and rotors are covered with a safety shield, which may also serve to reduce air friction and facilitate temperature control. Such units are normally equipped with a timer, tachometer, and manual or automatic braking. Samples may be mixed with the medium prior to loading, or layered on top of a homogeneous medium or density gradient. Bottle centrifuges are usually bench-top units that may operate at speeds up to 30 000 rpm and g_{\max} of 65 000, but are also available as larger, free-standing units that generate centrifugal forces in excess of 100 000 g . Sample capacities range from capillary tube to 1 L bottles (4 L total capacity).

Bottle-centrifuge rotors classified as swinging-bucket, fixed-angle, and vertical (Figure 7). In the *swinging-bucket* type, the bottles are in a vertical position at rest but swing outward to a horizontal

orientation as the rotor speed increases. In this orientation, the centrifugal force is applied along the length of the tube, making them suitable for rate separations. They may also be used for batch separation of immiscible liquids with some rotors specifically designed to hold separatory funnels to facilitate post-run recovery. However, their high k -factors make them generally unsuitable for differential pelleting, though some rotors constructed to hold short, large-diameter bottles, are designed for such purposes. *Fixed-angle* rotors are loaded and operated in a similar manner except that, as the name implies, the tube remains at a fixed angle both at rest and during the run. The fixed angle is typically 20–45° from the vertical, though *near-vertical* rotors are less than 10° from the vertical. The fixed-angle design provides a shorter pathlength (Figure 7) with a corresponding reduction in run time (lower k -factor). Particles that reach the outer wall of the tube during the run aggregate and quickly slide down the tube wall to form a pellet in the bottom. This makes the fixed-angle rotor useful for both pelleting (Figure 3) or isopycnic banding (Figure 4). *Vertical* rotors can be considered as an extension of fixed-angle rotors in which the angle of repose is 0° from the vertical. In this design, the maximum pathlength is equal to tube diameter, thereby providing the lowest k -factors for a given tube size. Vertical tube rotors are commonly used for isopycnic banding where short run times are important, as compared to near-vertical rotors, which provide short pathlengths yet permit pellet accumulation.

The tubes loaded into both vertical and fixed-angle rotors must be sealed during the run to prevent the contents from escaping as the medium moves up the outer wall at speed. O-ring sealing systems or heat sealing are commonly used. If the volume is kept sufficiently low, this step may not be necessary except to prevent the escape of hazardous aerosols, in which case a plastic screw or push-on cap may suffice.

For pelleting runs, sample recovery entails decanting the supernatant from the top and scrapping or washing the pellet into a recovery vessel or filter. For density-gradient runs, the sample may be unloaded from either the top or bottom of the tube with a pump, a Pasteur pipette, syringe, displacement liquid, etc., or by using soft plastic tubes that may be pierced to facilitate recovery of a targeted central band.

Zonal Rotors

While bottle centrifuges can be, and are, effectively used for density-gradient centrifugation, their

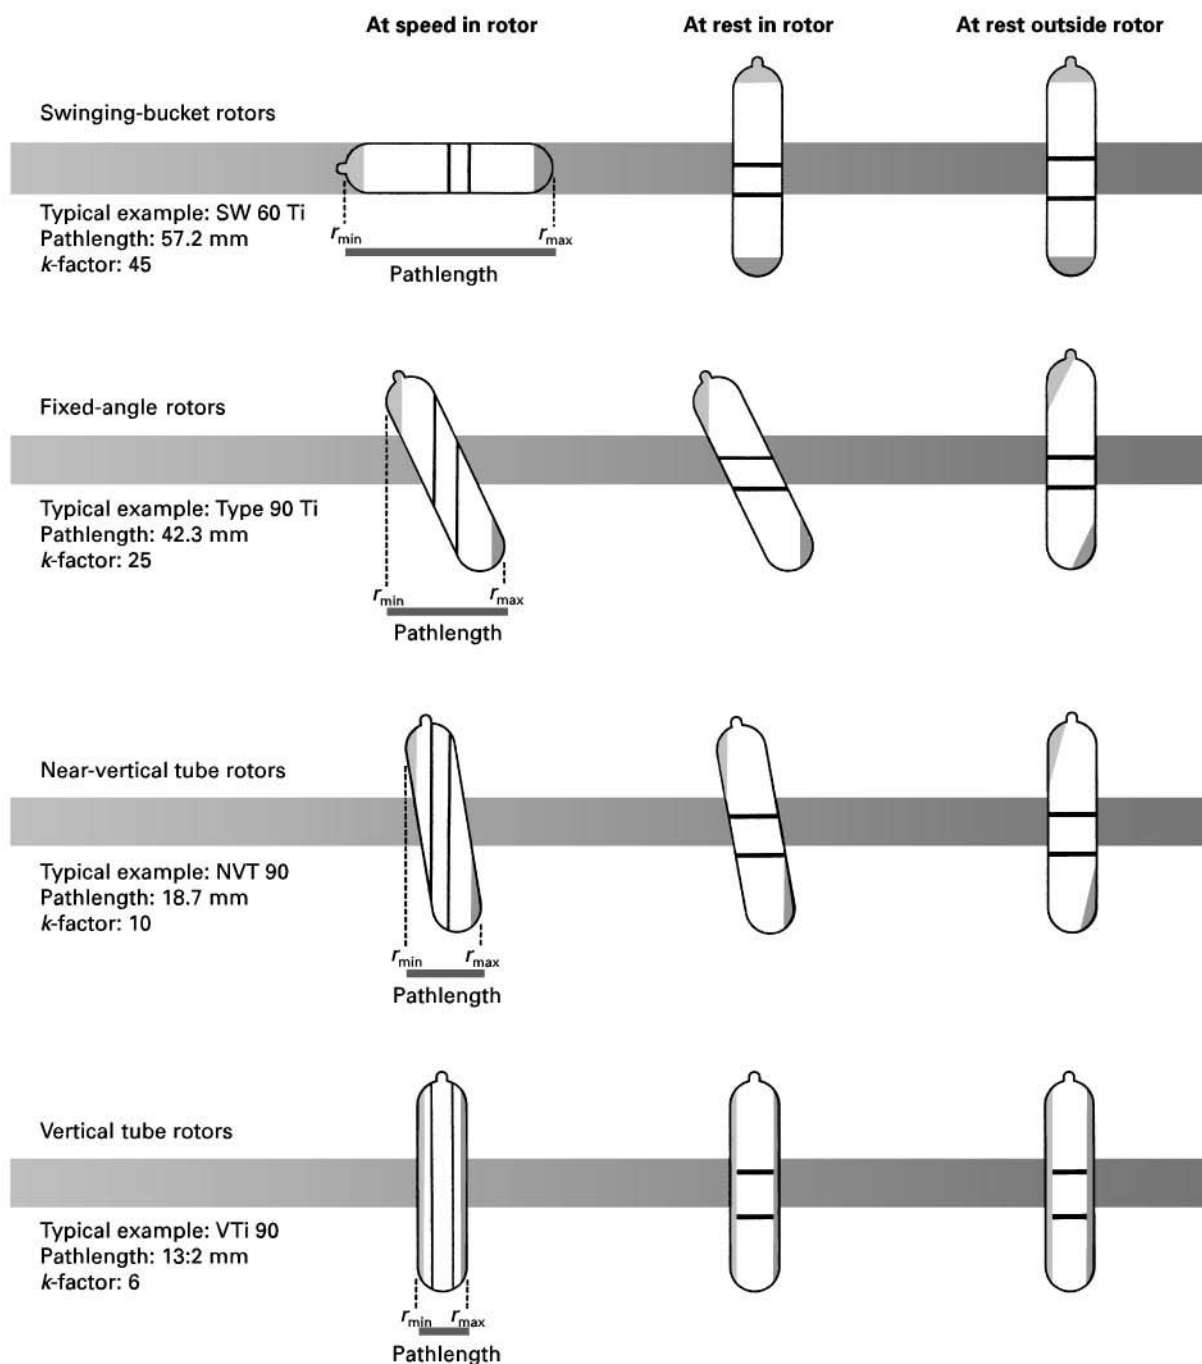

Figure 7 Particle separation in swinging-bucket, fixed-angle and vertical-tube rotors. Dark shading represents pelleted material, light shading in floating components, and band are indicated by black lines. (Courtesy of Beckman Instruments, Inc.)

capacity may be insufficient for certain applications. This obstacle may be addressed with zonal rotors, which provide a larger internal volume for a given radius. Zonal rotors are bowls or cylindrical cavities equipped with a central core and attached vanes or septa that divide the rotor into four or more sector-shaped compartments. Zonal rotors present additional advantages over bottle centrifuges such

as minimal wall effects, maximum particle and gradient resolution during sedimentation and recovery, rapid gradient formation, and high rotation speeds. Due to their higher efficiency and capacity, zonal rotors are widely utilized in applications ranging from separation/purification of proteins, viruses and subcellular components to the concentration of coal or kerogen macerals. Zonal centrifuges

can be operated in batch, semi-batch, or continuous modes and may be loaded or unloaded with the rotor stopped (*static*) or with the rotor spinning (*dynamic*).

Statically loaded and unloaded zonal rotors are also called reorienting gradient rotors. In this method, the gradient is loaded with the rotor at rest then slowly accelerated to permit the gradient to reorient from a horizontal to a vertical configuration, as illustrated in **Figure 8**. Solutions of increasing density are loaded to the bottom with the sample solution layered on top after the rotor is filled. When the rotor is accelerated, the gradient reorients to a vertical position with the lighter fractions and sample in the centre of the rotor. After centrifugation, the rotor is slowly decelerated and the gradient returns to a horizontal orientation. The heavier fractions may be removed first by displacement with air or the rotor lid removed and the gradient pumped out. Alternatively, the gradient may be displaced with a denser liquid that forces the lighter fractions out first. The advantages of the reorienting gradient technique are simplicity and the avoidance of rotating seals that may leak or fail during dynamic loading/unloading. The major disadvantage is the tendency of the gradient to swirl as it reorients, leading to a loss in resolution.

Dynamic loading and unloading, also known as 'rotating seal', is conducted as the rotor spins, as illustrated in **Figure 9**. The gradient is pumped through a rotating seal in the centre of the rotor lid into passages machined into the rotor core, which channel the solutions to the outer wall. The lighter-density solutions are loaded first, forming a vertical layer that is displaced inward by the ensuing denser solutions. An optional high density liquid *cushion* may be added last if a reduction in the effective rotor volume is desired. The sample is introduced to the centre of the rotor by reversing the feed/exit lines. The rotor is accelerated to the operating speed for a targeted time, then decelerated to the initial loading speed. In centre unloading, a high density immiscible liquid, such as Fluorinert™, may be routed to the outer wall, forcing the gradient from the rotor, lighter fractions first. Edge unloading is similar, only a light liquid is pumped to the centre, displacing the heavier fractions first. The gradient may be fractionated as it exits by routing the effluent through a programmable fractionator that automatically switches collection vessels, or manually by selecting cutoff points with a density meter, refractometer or UV absorption cell, or by collecting predetermined volumes. While somewhat more cumbersome, dynamic loading generally provides better resolution than static loading/unloading.

Ultracentrifuges

'Ultracentrifuge' is an ill-defined term applied to centrifuges with rated speeds greater than about 25 000 rpm, regardless of the medium or rotor design. While speed was historically used to designate ultracentrifugation, some manufactures now reserve this term for centrifuges that operate at sufficient speeds to require a vacuum to reduce frictional drag and/or rotor heating. Most such units are also equipped with refrigerant capability for the same purpose.

Ultracentrifuges are classified as preparative or analytical. Preparative ultracentrifuges are used to separate and recover purified sample components at speeds ranging up to 150 000 rpm and forces to 900 000*g*. The rotor configuration may be any of the types described in this section – bottle, zonal, or continuous – with fixed-angle and vertical-bottle centrifuges providing the highest speeds and titanium being the most common material of construction.

Analytical ultracentrifuges, originally developed by Svedberg, are used to study the behaviour of particles during sedimentation. While analytical rotors are available in various shapes and sizes, their defining feature is a transparent window, typically constructed of quartz or sapphire, that permits the sedimenting particles to be monitored optically during the run. UV absorption and/or refractive index measurements are the most common monitoring techniques. The required sample volume is low, ranging down to 5 µL, making this a useful technique when sample availability may otherwise be a limiting factor. Sample recovery is generally a secondary consideration, if conducted at all. Analytical ultracentrifuges are available at speeds up to 70 000 rpm and centrifugal forces in excess of 350 000*g*.

Continuous Centrifuges

Conventional batch separations are generally unsuitable for many industrial and certain laboratory-scale separations. Continuous-flow centrifugation offers certain advantages when large quantities of sample must be processed, the stream to be recovered is at low concentration, or long acceleration/deceleration times are required. Such units may be used for rate, pelleting, filtration, or isopycnic banding separations. In continuous-flow centrifugation, the sample mixture is introduced continuously to a spinning rotor as the supernatant stream continuously exits. The denser product may either accumulate on the rotor wall, from where it is recovered by stopping the run when the rotor capacity is reached (semi-batch mode), or continuously discharged during the run (continuous mode).

Figure 9 Dynamic loading and unloading of a zonal rotor. (Courtesy of Beckman Instruments, Inc.)

The rotors previously described can be, and often are, adapted for continuous-flow separations. However, the following discussion focuses on rotors that are designed specifically for continuous operation, particularly for industrial applications such as those depicted in **Figure 10**.

Disc centrifuges Disc centrifuges operate on the principle of differential sedimentation and are used for two-phase (liquid–solid or liquid–liquid) and three-phase (liquid–liquid–solid) separations. These are highly efficient units with some industrial-scale units generating forces of 10 000*g* and pelleting of particles as small as 0.1 μm . Disc centrifuges are essentially a rotating bowl equipped with an internal set of conical settling plates or discs mounted at an angle to the axis of rotation (typically 30–40°). The discs serve to decrease the sedimentation pathlength and increase the sedimentation surface area, i.e. capacity factor. Denser materials sediment onto and slide across the plate surfaces before accumulating on the bowl wall (**Figure 11**) as the clarified supernatant

continuously exits. In addition to the parameters of centrifugal force and flow rate, the capacity and performance of disc centrifuges are also dependent on the number, spacing and diameter of the plates. Sample mixtures may be introduced to either the interior or outside of the disc stack, depending on the nature and concentration of solids, with most units configured for liquid–liquid or liquid–liquid–solid mixtures being centre fed.

Three variations of disc centrifuges, as distinguished by their solids-handling capability, are commonly used: solids-retaining, intermittent solids-ejecting and continuous solids-ejecting (**Figure 11**). Solids-retaining designs (**Figure 11A**) are appropriate for liquid–solid or liquid–liquid separations where the solids content is less than about 1% by volume. For liquid–solid separations, the solids that accumulate on the bowl wall are recovered when the rotor capacity is reached and the centrifuge is stopped. Removable baskets are incorporated into some designs to facilitate solids removal. Recovery of two liquid streams can be achieved by positioning exit

Clarification Separate suspended particles from a liquid

Purification Separate immiscible liquids (even with solids present)

Dewatering Concentrate a slurry

Classification To split a suspension into two streams with different particle size distributions

Washing Countercurrent washing or dissolving of impurities in suspended, crystallized or amorphous solids

Extraction To mix a liquid containing a mineral or extract with a liquid agent, and then separate out the agent, which contains the extract or mineral

Figure 10 Major industrial applications for continuous centrifuges. (Courtesy of Alfa Laval Separations.)

ports at different radial distances as dictated by the relative concentration of the liquids. Commercial units are available with liquid throughput capacities of $60 \text{ m}^3 \text{ h}^{-1}$ and holding capacities of 30 L. A variation on the solids-retaining disc centrifuge is the cylindrical-bowl design shown in **Figure 12**, which incorporates a series of concentric cylindrical retainers for processing liquid–solid mixtures. Unlike the disc centrifuge, in which the feed stream is split and makes a single pass through the disc stack, in the cylindrical-bowl design the liquid stream is routed through each chamber in succession, resulting in a longer residence time, more efficient recovery, and generally greater capacity (to 70 L). Applications of solids-retaining centrifuges of the stacked-disc or cylindrical-bowl design include separation of cream from milk, organic waste from water, purification of lubricating oils, or removal of water and solids from jet fuel.

Solids-ejecting stacked-disc centrifuges (**Figure 11B**) are more suitable for processing samples with solids contents to about 15% by volume. These units operate similarly to the solids-retaining design, only solids or sludge that accumulate on the bowl wall are intermittently discharged through a hydraulically activated, peripheral opening. Laboratory models to 18 cm diameter and industrial units to 60 cm are available, with the latter capable of throughputs in excess of $100 \text{ m}^3 \text{ h}^{-1}$. Applications for these units include catalyst recovery, clarification of paints and varnishes, treatment of radioactive waste water, and copper extraction.

Continuous solids-discharge disc centrifuges, also called nozzle bowl separators (**Figure 11C**), are used to process samples with solids contents ranging from 5 to 30% by volume. In this design, solids are continuously discharged via backward-facing orifices, i.e. nozzles, closely spaced around the outer periphery of

Figure 11 Disc centrifuge configurations: (A) solids-retaining; (B) intermittent solids-ejecting; and (C) continuous solids-ejecting. (Courtesy of Alfa Laval Separations.)

the bowl. Due to the high discharge velocities resulting from the centrifugal pressures, nozzle erosion can occur. Thus, the materials used for nozzle construction and the ease of replacement of eroded components should be considered. Newer designs discharge to an internal chamber where the discharge is pumped out as a product stream. Industrial units are available to $200 \text{ m}^3 \text{ h}^{-1}$ throughput capacity, elevated temperature ($\leq 200^\circ\text{C}$) or pressure (7 bar) capability, and particle removal to $0.1 \mu\text{m}$. Applica-

tions for continuous-discharge disc centrifuges include production of baker's yeast, dewatering of kaolin clay, titanium dioxide classification, and coal-tar and tar-sand clarification.

Continuous conveyor discharge These centrifuge types integrate an active mechanical solids discharge mechanism in an imperforate bowl for the continuous processing of larger sample volumes. The bowl shape is tubular, having a length-to-diameter ratio of 1.5–5.2, and may operate in either a horizontal or vertical configuration. The vertical configuration is generally preferred for reduced or elevated temperature and/or pressure applications owing to fewer mechanical problems with seals and heat expansion. The solids-discharge mechanism is most commonly, a helical screw turning at a slightly slower rate than the rotor, though pistons or conveyer belts are also used. **Figure 13** illustrates a helical-screw configuration used for three-phase separations (liquid–liquid–solid). Solid–liquid and liquid–liquid configurations with either concurrent or countercurrent flow regimes are commercially available. Such mechanical discharge units typically operate at lower centrifugal forces (to $5000g$) than disc centrifuges. However, they are capable of very high throughput, up to $300\,000 \text{ L h}^{-1}$, and can be used to process feed streams containing up to 50% solids by volume. While a limited number of industrial units operate on materials smaller than $1 \mu\text{m}$, particles smaller than about $2 \mu\text{m}$ are usually not collected in such units, a characteristic that is used to advantage for particle classification. Continuous conveyor centrifuges are widely used in the chemical, mining, pharmaceutical,

Figure 12 Schematic of a cylindrical-bowl centrifuge. (Courtesy of Alfa Laval Separations.)

Figure 13 Schematic of a horizontal continuous-conveyor centrifuge. (Courtesy of Alfa Laval Separations.)

biotechnology and food sectors for clarifying, classifying, dewatering and thickening applications.

Tubular centrifuges These centrifuges utilize a vertically mounted, imperforate cylindrical-bowl design to process feed streams with a low solids content. Liquid(s) is discharged continuously and solids are manually recovered after the rotor capacity is reach-

ed. One configuration, designed for recovery of two immiscible liquids and a solid product, is shown in **Figure 14**. Other configurations for processing solid-liquid or liquid-liquid mixtures are also widely used. Industrial models are available with diameters up to 1.8 m, holding capacities up to 12 kg, throughput rates of $250 \text{ m}^3 \text{ h}^{-1}$, and forces ranging up to $20\,000g$. Laboratory models are available with

Figure 14 A tubular centrifuge configured for recovery of two liquids and one solids stream. (Courtesy of Alfa Laval Separations.)

diameters of 4.5 cm, throughput rates of 150 L h^{-1} , and centrifugal forces ranging up to $62\,000g$. Because of their high speed and short settling path, tubular centrifuges are well suited for the pelleting of ultrafine particles, liquid clarification, and separation of difficult-to-separate immiscible liquids. In addition to the standard electric motor used for most laboratory centrifuges, laboratory-scale tubular centrifuges are available with turbine drives. Tubular centrifuges were refined for the separation of penicillin during World War II but since then have largely been replaced by disc centrifuges because of their limited holding capacity. However, they are still widely used for applications that involve the efficient recovery of high value products at high purity, especially in the pharmaceutical and chemical industries. Typical applications include recovery of *Escherichia coli* cells and flu viruses, removal of colloidal carbon and moisture from transformer oils, removal of small particles from lubricating oils, blood fractionation, and de-inking.

Continuous zonal rotors Zonal rotors are often used for smaller scale, semi-batch separations. Operation is similar to that previously described for batch separation only a larger diameter core with a different flow pattern is inserted as illustrated in **Figure 15**. Continuous-feed separations in zonal centrifuges are best suited for low concentration, high volume samples. Such separations may be conducted with a homogeneous medium for sample pelleting, or with a density gradient for materials that may be adversely affected by pelleting (e.g. viruses that may lose their activity) or if simultaneous isolation of two or more materials is desired. Applications include purification of viruses from tissue-culture media, harvesting bacteria, or separating fine clay particles in water pollution studies.

Elutriation rotors Another type of laboratory-scale continuous-flow centrifugation is elutriation or counterstreaming, used to separate particles with differing sedimentation rates (rate separation). A schematic of the elutriation process is shown in **Figure 16**. Conical or funnel-shaped rotors are used with the small end positioned farthest from the axis of rotation. The rotor is initially filled with a buffer solution followed by the sample mixture, introduced at a constant rate to the small end of the spinning rotor, where particles experience the opposing forces of the centrifugal field and the flowing medium. Initially, the frictional force of the carrier medium is greater than the centrifugal force and all particles are swept inward by the flowing carrier. However, as the entrained particles migrate toward the large end of

Figure 15 Flow regimes in a continuous-flow zonal rotor. (Courtesy of Beckman Instruments, Inc.)

the chamber, the linear velocity of the carrier decreases as the cross-sectional area of the rotor increases. Due to the greater sedimentation rates for larger particles in a centrifugal force field, smaller particles continue to migrate toward the centre of the rotor while larger particles remain suspended or move more slowly, resulting in particle classification. Such separations are semi-batch since, as the concentration of larger particles in the rotor increases to capacity, sample feed must be stopped so that these particles may be eluted with a higher velocity rinse solution. Elutriation rotors typically operate at lower centrifugal forces ($10\,000g$) with throughputs to 400 mL min^{-1} . A common application is the isolation of specific cell types.

Figure 16 The elutriation process. (Courtesy of Beckman Instruments, Inc.)

Centrifugal Filtration Equipment

In centrifugal filtration, centrifugal force is used to press a solids suspension against a filter medium that permits the mother liquor to pass while retaining the solid particles. Such centrifuges are used for the separation of solids from liquid slurries, chiefly in industrial applications, and are usually characterized in terms of the final moisture content, drainage time and centrifugal force. In addition to the centrifugal field, the drain or screen area and cake thickness are the primary controllable parameters that govern performance. Filtration centrifuges are available in numerous configurations with units often designed or modified for a specific application. Three of the more common designs are batch/semi-batch basket centrifuges, continuous push-type and continuous conical centrifuges.

Basket centrifuges The simplest and most common centrifugal filtration units are basket centrifuges. They are particularly useful when the nature or concentration of the solids varies substantially with time or for the recovery of small or difficult-to-filter particles. Basket centrifuges incorporate a perforated cylindrical bowl that is lined with a filtration medium, usually a fabric or metal screen. Industrial units generally spin at relatively low rates (<4000 rpm), are available with bowl diameters ranging from 0.3 m to 2.4 m, and may be operated at elevated temperatures (350°C) and/or pressures (1 MPa). The slurry is fed to the centre of the basket with the mother liquor passing and the cake accumulating against the filtration medium. When the accumulated cake volume is sufficient either to retard further filtration or unbalance the centrifuge, the solids must be discharged. This is achieved in one of three ways: (1) the centrifuge is stopped and the cake is manually scraped, useful for smaller batches when production does not warrant the additional costs of automation,

for processing different materials in a single unit, or when the equipment must be sterilized between batches; (2) the cake is mechanically unloaded at reduced speed by using a single or multiple plow; or (3) the cake is continuously removed at speed with a hydraulic *knife* in a *peeler* centrifuge, most useful for moderate production rates and for materials that drain freely. Other basket centrifuges, termed *inverting filter* centrifuges, have flexible filters that may be inverted to discharge the accumulated solids.

Continuous centrifugal filters are more useful for higher volume processing of fast-draining solids in applications that do not require a low level of moisture in the recovered product. They can be further divided into push-type (cylindrical) and conical filters.

Push-type centrifugal filters These units consist of a rotating cylindrical drum that incorporates a feed funnel that rotates with the drum. The slurry is introduced via the feed funnel where it is accelerated before being deposited to one end of the drum. Liquids pass through a cylindrical screen under centrifugal pressure as the solids accumulate to form a cake. The cake is then pushed by a reciprocating piston toward the exit located at the opposite end of the drum. Push-type filters may be single or multiple stage, with the latter incorporating a cylindrical screen with two to six variable-diameter steps. The diagram of a multistage push-type filter in **Figure 17** illustrates the integration of filtration and rinse cycles in a continuous operation.

Conical centrifugal filters In a conical centrifugal filter, the slurry is introduced to the small end of a conical drum, which supports the filtration medium. Liquids drain through the drum filter as the solids are either mechanically or self-discharged through the large end. The movement of the solids from the small end of the cone to the larger-diameter end results in a thinning of the cake that facilitates

Figure 17 Multistage push-type centrifugal filter. (Courtesy of Alfa Laval Separations.)

drainage. Some designs incorporate a lower cone angle at the small end, where most of the drainage occurs, and a higher angle on the large end, to increase the solids-holding capacity and provide additional drainage time.

Three methods of solids removal are commonly used for conical filtration: screw conveyor, self-discharging or vibratory. Screw conveyers consist of a vertical or horizontal conical bowl with an internal helical screw rotating slightly faster than the conical drum. In this configuration, solids are continually moved from the small end of the cone and discharged from the larger end. Screw-conveyer units have cone angles that generally range from 10–20°, feed capacities of 1–15 m³ h⁻¹, and centrifugal forces to 3500*g*. Applications include the dewatering of crystalline solids and the extraction of solids from fruit and vegetable pulps. Self-discharging filters are similar to screw conveyers, only the cone angle is larger (20–35°) than the angle of repose of the cake. At these greater angles, the solids slide down the tapered walls and exit the large end of the conical drum without the need for mechanical assistance. Vibratory-discharge filters are also similar in design to screw-conveyer units, but in this case solids discharge is accomplished by applying a vibratory or oscillatory motion to the bowl or casing. Such units are typically operated at low speeds (300–500 rpm) and used to process larger particles (0.25–30 mm) than screw-conveyer or self-

discharging designs. The cone angle is 13 to 18° with throughput capacities of 25–150 t h⁻¹. Their most common application is for the dewatering of coal fines.

Introduction

Chromatography is the most widely used separation technique in chemical laboratories, where it is used in analysis, isolation and purification, and it is commonly used in the chemical process industry as a component of small and large-scale production. In terms of scale, at one extreme minute quantities of less than a nanogram are separated and identified during analysis, while at the other, hundreds of kilograms of material per hour are processed into refined products. It is the versatility of chromatography in its many variants that is behind its ubiquitous status in separation science, coupled with simplicity of approach and a reasonably well-developed framework in which the different chromatographic techniques operate.

Chromatography is essentially a physical method of separation in which the components of a mixture are separated by their distribution between two phases; one of these phases in the form of a porous bed, bulk liquid, layer or film is generally immobile (stationary phase), while the other is a fluid (mobile phase) that percolates through or over the stationary phase. A separation results from repeated sorption/desorption events during the movement of the sample components along the stationary phase in the general direction of mobile-phase migration. Useful separations require an adequate difference in the strength of the physical interactions for the sample components in the two phases, combined with a favourable contribution from system transport properties that control sample movement within and between phases. Several key factors are responsible, therefore, or act together, to produce an acceptable

separation. Individual compounds are distinguished by their ability to participate in common intermolecular interactions in the two phases, which can generally be characterized by an equilibrium constant, and is thus a property predicted from chemical thermodynamics. Interactions are mainly physical in type or involve weak chemical bonds, for example dipole-dipole, hydrogen bond formation, charge transfer, etc., and reversible, since useful separations only result if the compound spends some time in both phases. During transport through or over the stationary phase, differential transport phenomena, such as diffusion and flow anisotropy (complex phenomena discussed later), result in dispersion of solute molecules around an average value, such that they occupy a finite distance along the stationary phase in the direction of migration. The extent of dispersion restricts the capacity of the chromatographic system to separate and, independent of favourable thermodynamic contributions to the separation, there is a finite number of dispersed zones that can be accommodated in the separation. Consequently, the optimization of a chromatographic separation depends on achieving favourable kinetic features if success is to be obtained.

The Family of Chromatographic Techniques

A convenient classification of the chromatographic techniques can be made in terms of the phases employed for the separation (**Figure 1**), with a further subdivision possible by the distribution process employed. In addition, for practical utility transport processes in at least one phase must be reasonably fast; for example, solid–solid chromatography, which may occur over geological time spans, is impractical in the laboratory because of the slow migration of

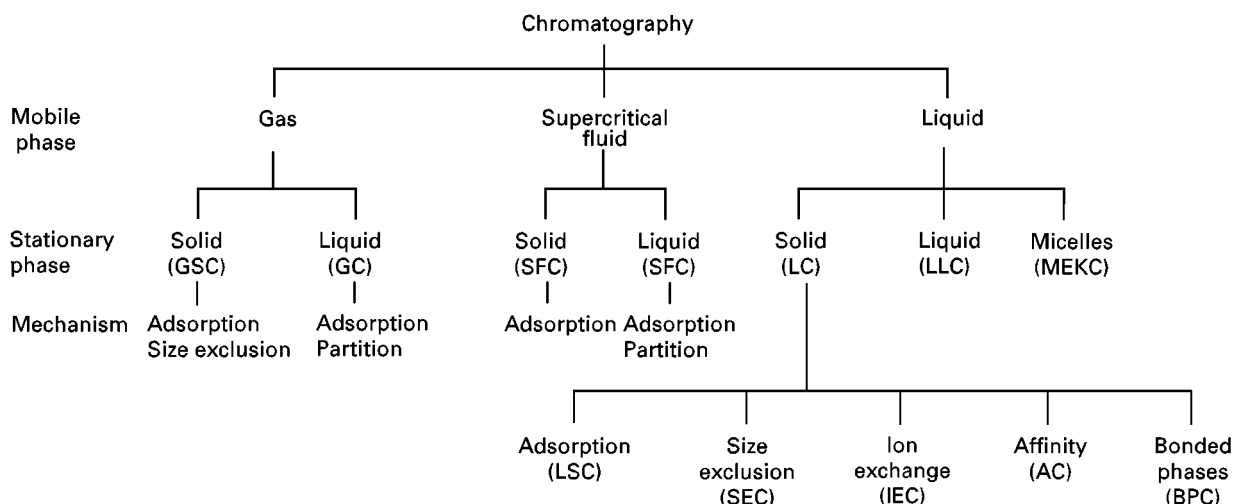

Figure 1 Family tree of chromatographic methods.

solutes through the crystal lattice. Two distinct phases are required to set up the distribution component of the separation mechanism, which explains why gas-gas chromatography does not exist and liquid-liquid separations are restricted to immiscible solvents. When the mobile phase is a gas the stationary phase can be a liquid or a solid and the separation techniques are called gas-liquid chromatography (GLC) and gas-solid chromatography (GSC). The simple term GC encompasses both techniques but, unless otherwise specified, it usually means GLC since this is the most common arrangement. Separations in GLC occur because of differences in gas-liquid partitioning and interfacial adsorption. In GSC the retention mechanism is governed by interfacial adsorption or size exclusion, if a solid of controlled pore size, such as a zeolite, is used as the stationary phase. When the mobile phase is a supercritical fluid (SFC) the stationary phase can be a liquid or a solid, and the distribution process may be interfacial adsorption or absorption.

When the mobile phase is a liquid the stationary phase can be a solid (liquid-solid chromatography, LSC) with interfacial adsorption as the dominant distribution process; a solid of controlled pore size (size exclusion chromatography, SEC), in which the distribution constant is characteristic of the ratio of the solute size to the dimensions of the stationary phase pore sizes; a solid with immobilized ionic groups accessible to solutes in the mobile phase with electrostatic interactions as the dominant distribution process (ion exchange chromatography or ion chromatography, IEC or IC); a solid with immobilized molecular recognition sites accessible to the analyte in the mobile phase (affinity chromatography, AC) in which the dominant distribution process

is the three-dimensional specificity of the molecular interactions between the receptor and the analyte (a technique used in biotechnology); a porous solid coated with a film of immiscible liquid (liquid-liquid chromatography, LLC) in which the dominant distribution process is partitioning; or a solid with a surface containing organic groups attached to it by chemical bonds (bonded-phase chromatography, BPC) in which the dominant distribution processes are interfacial adsorption and partitioning.

Bonded phases in liquid chromatography are widely used to tailor solid phases for different applications, including LSC, SEC, IEC, IC and AC (Figure 2). Reversed-phase chromatography (RPC) is a particular form of bonded-phase chromatography in which the mobile phase is more polar than the stationary phase (for most practical applications the mobile phase is an aqueous solution). It is the most popular form of liquid chromatography because of its broad applicability to neutral compounds of wide polarity. In addition, by exploiting secondary chemical equilibria weak acids and bases can be separated by pH control (ion suppression chromatography, ISC); ionic compounds by using ion pairing with an additive of opposite charge (ion pair chromatography, IPC); and metal ions by the formation of neutral complexes (metal-complexation chromatography, MCC). By adding a surfactant to the mobile phase, micelles can be used to modify the overall distribution constant (micellar liquid chromatography, MLC), and a totally aqueous buffered mobile phase and a decreasing ionic strength gradient can be used to separate biopolymers with minimal disruption of conformational structure (hydrophobic interaction chromatography, HIC). Bonded-phase chemistry is also commonly employed to prepare stationary

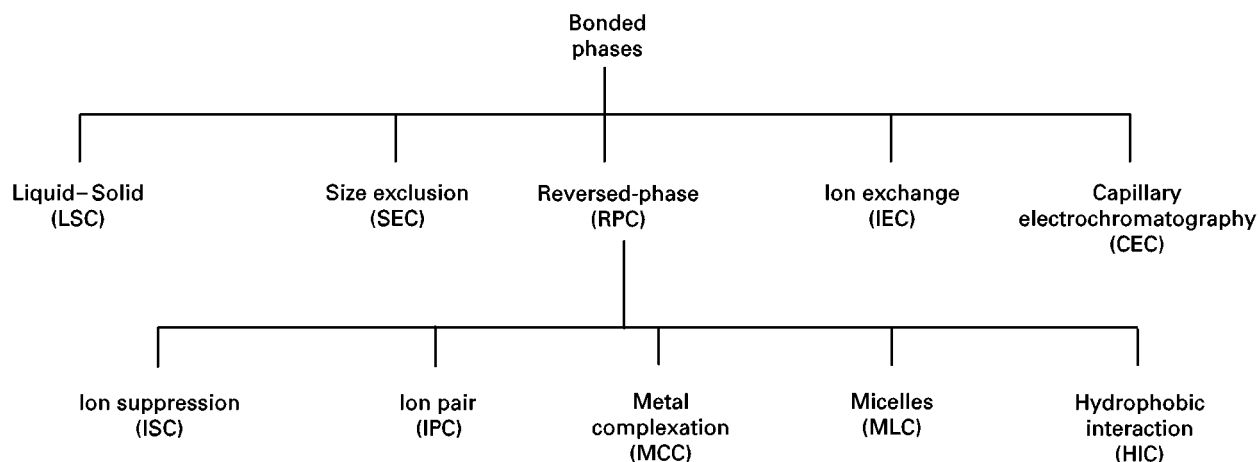

Figure 2 Applications of bonded phases in LC.

phases with immobilized enantiomer-selective groups for the resolution of racemates by chiral chromatography.

The mobile phase can be transported through or over the stationary phase by application of external pressure when the stationary phase is enclosed in a rigid container, or column. This is the ordinary mode of gas, supercritical fluid and liquid chromatography. If the stationary phase is distributed as a thin layer on a (usually) flat support, such as a sheet of glass or plastic, and the mobile phase is allowed to ascend through the layer by capillary forces, then this method is referred to as planar or thin-layer chromatography (TLC). The fundamental basis of the distribution mechanism between the mobile phase and the stationary phase is identical to that described for column liquid chromatography, only the separation format and transport mechanism for the mobile phase are different. TLC has largely superseded paper chromatography (PC) in contemporary practice. PC is mechanistically identical to TLC but, with a few exceptions, provides poorer separation characteristics. Bulk flow of liquid mobile phases containing an electrolyte can also be transported through a column by an electric field, through the process known as electroosmosis. When a column packed with a stationary phase is used this is called electrochromatography, or since columns of capillary dimensions are essential for this technique, capillary electrochromatography (CEC). The distribution process for neutral solutes is independent of the transport process, and separations occur by the mechanisms indicated for liquid chromatography. Ionic surfactants can form micelles as a continuous phase dispersed throughout a buffer. In an electric field these charged micelles move with a different velocity or direction to the flow of bulk electrolyte. Neutral

solutes can be separated, if their distribution constant between the micelles and buffer are different, by micellar electrokinetic chromatography (MEKC). The stationary phase in this case is referred to as a pseudo-stationary phase, since it is not stationary, but moves with a different velocity to the mobile phase. Ionic solutes in CEC and MEKC are influenced by the presence of the electric field and are separated by a combination of chromatography and electrophoresis.

Mode of Zone Displacement

In nearly all chromatographic systems, transport of solute zones occurs entirely in the mobile phase. Transport is an essential component of the chromatographic system since the most common arrangement for the experiment employs a sample inlet and a detector at opposite ends of the column, with sample introduction and detection occurring in the mobile phase (GC, SFC, LC, MEKC). In planar chromatographic systems (TLC, PC), sample introduction and detection is performed in the stationary phase, but the detection is of solute zones that have been transported different distances by the mobile phase. In GC the movement of solute molecules from the stationary to the mobile phase is controlled by the vapour pressure of the solutes in the column, and is usually manipulated by varying temperature. At an optimum temperature sample molecules will spend some of their time in the mobile phase, where they will be transported through the column, and some time in the stationary phase, where they are differentiated by their capacity for intermolecular interactions with the stationary phase. Displacement of solute zones can be achieved in three distinct ways: frontal analysis, elution and displacement (Figure 3).

Figure 3 Mode of zone displacement in chromatography.

In frontal analysis, the mobile phase introduces the sample continuously onto the column (or the sample is the mobile phase) until eventually the column is saturated with the sample and the component with the lowest affinity for the stationary phase is displaced from the column by sample components of greater affinity. When the zone of pure component has completely exited the column it is followed by a mixture containing the next component, and so on. Frontal analysis can be used to obtain thermodynamic data from chromatographic measurements and to isolate a less strongly retained trace component from a major component. However, quantitation for each component in a mixture is difficult, and at the end of the experiment the column is contaminated by the sample so that reuse requires stripping the sample from the column.

In displacement chromatography the sample is applied to the column as a discrete band and a substance (or mobile-phase component) with a higher affinity for the stationary phase than any of the sample components is continuously passed through the column. The displacer pushes sample components down the column and, if the column is long enough, a steady state is reached. A succession of rectangular bands of pure components then exits the column. Each component displaces the component ahead of it, with the last and most strongly retained component

being forced along by the displacer. At the end of the separation the displacer must be stripped from the column if the column is to be reused. Displacement chromatography is used mainly in preparative and process chromatography, where high throughputs of pure compounds can be obtained (note that the contact boundary between zones may not be discrete and the collection of pure compounds may be restricted to the central region of the displaced zones).

In elution chromatography the sample is applied to the column as a discrete band and sample components are successively eluted from the column diluted by mobile phase. The stationary and mobile phases are normally at equilibrium prior to sample introduction. The mobile phase must compete with the stationary phase for the sample components; separation will only occur if the distribution constants for the various components, resulting from the competition, are different. Elution chromatography is the most convenient method for analysis and is the most common method of separation in GC, SFC, LC and MEKC. Development, a modification of the elution mode, is used in planar chromatography. Samples are applied to the dry layer as compact spots or bands and the layer subsequently contacted by the mobile phase, which ascends and moves the sample components to positions higher up the layer in the direction of mobile-phase flow. The separation is (usually) stopped before the mobile phase reaches the opposite edge of the layer and neither the eluent nor the sample components exit the layer. The two processes can be compared; all components travel the same distance and are separated in time using the elution mode in column chromatography, whereas all components have the same separation time and are separated in space (migration position) in planar chromatography using the development mode.

Chromatogram

The information obtained from a chromatographic experiment is contained in the chromatogram. When the elution mode is used this consists of a plot of the concentration or mass profile of the sample components as a function of the flow of the mobile phase or as a function of time. Typically the y-axis will be detector response and the x-axis time or volume of mobile phase in column chromatography or migration distance in planar chromatography. The position of each peak in the chromatogram is characteristic of the identity of the compound and the area under the peak is a function of the concentration or amount of each compound. Peak widths in the chromatogram are controlled by solute-dependent kinetic factors, which in turn can be used to deduce values for

Figure 4 Calculation of the R_F value in planar chromatography. Z_x distance moved by the sample from the sample origin; Z_0 distance between the solvent entry position and the sample origin; Z_f distance between the solvent entry position and the solvent front.

characteristic physical properties of either the solute or the mobile and stationary phases.

The position of a peak in the chromatogram is made up of two contributions: (1) the time (or volume of mobile phase) required by a compound that does not interact with the stationary phase to reach the detector from the sample inlet, called the column hold-up time or dead time; and (2) the time that individual compounds spend in the stationary phase (all compounds spend the same time in the mobile phase). The column hold-up time is a feature of the experimental system and is not fundamentally related to solute properties. Because of this, retention time is not a useful parameter for column comparisons. A more useful term is the retention factor (previously known as the capacity factor), k , defined as the ratio of the time the solute spends in the stationary phase to the time it spends in the mobile phase. The ratio of the retention factors for two solutes is called the separation factor, α , which by convention is always expressed with the larger retention factor in the numerator ($\alpha \geq 1$). The separation factor expresses the ease with which the chromatographic system can separate two compounds, and is directly related to the difference in free energy for the interactions of the two compounds in the chromatographic system. It is a major optimization parameter, as we shall see later. In planar chromatography retention is usually expressed as the retardation factor, R_F , equivalent

to the ratio of the distance migrated by the solute zone, Z_x , to the distance moved by the solvent front, $Z_f - Z_0$, measured from the sample application position, ($1 \geq R_F \geq 0$), as illustrated in **Figure 4**. The planar chromatographic retardation factor and the column retention factor are simply related by $k = (1 - R_F)/R_F$.

Peak Shape Models

For an ideal separation the peaks in the chromatogram are usually considered to be Gaussian. This is a convenient, if not always accurate, model and peak asymmetry can arise from a variety of instrumental and chromatographic sources. The most common types of peak distortion are skewness (the peak front is sharper than the rear) and tailing (the rear of the peak is elongated compared to the front). Although instrumental sources of peak asymmetry should, of course, be minimized, chromatographic sources cannot always be avoided. Curve fitting by computer offers the possibility of deconvoluting chromatographic peak profiles into their individual contributions. The exponentially modified Gaussian function, obtained by the combination of a Gaussian function with an exponential decay function (that provides for the asymmetry in the peak profile), is often an acceptable description of chromatographic peaks in analytical applications.

Chromatographic sources of peak asymmetry result from mechanical effects, for example the formation of voids in the stationary-phase bed and excessive extra-column volumes, and from isotherm characteristics. Most of the theory of analytical chromatographic separations is based on a linear isotherm model where the compositions in the stationary and mobile phases are proportional and characterized by a distribution constant that is independent of sample size and composition (**Figure 5**). The peaks resulting from a linear chromatography model are symmetrical and can be characterized by a normal distribution. The width of the chromatographic zone is proportional to retention and can be obtained directly from peak shape considerations. The extent to which the properties of the chromatographic system contribute to zone broadening (peak widths) is given by the number of theoretical plates, N . For a normal distribution this is equivalent to $(t_R/\sigma_t)^2$, where t_R is the retention time and σ_t is the peak standard deviation in time units. Simple algebraic manipulation of this formula permits calculation of N from the peak width at base or half-height, etc. For column comparison purposes the height equivalent to a theoretical plate, H , equivalent to the column length divided by N , is generally used.

Figure 5 Influence of isotherm type on peak shapes.

Nonlinear isotherms (nonlinear chromatography) result in the production of asymmetric peaks. Langmuir isotherms are frequently observed for adsorption interactions on surfaces with an energetically heterogeneous distribution of adsorption sites with incompatible association/dissociation rate constants. For sorbents with monolayer coverage, Langmuir-type isotherms result when solute-stationary phase interactions are strong compared with solute-solute interactions. Because the interactions between solutes are comparatively weak, the extent of sorption decreases following monolayer formation, even though the concentration in the mobile phase is increasing. In this case the concentration of the component in the stationary phase at equilibrium is no longer proportional to its concentration in the mobile phase and the peak shape and retention time will depend on the sample composition and amount. Anti-Langmuir type isotherms are more common in partition systems when solute-stationary phase interactions are relatively weak compared with solute-solute interactions, or where column overload results from the introduction of large sample amounts. Such conditions are common in preparative chromatography, where economic considerations dictate that separations are optimized for production rate and to minimize mobile phase consumption and operating costs.

Flow through Porous Media

For an understanding of zone dispersion in chromatography, an appreciation of the mobile-phase linear velocity through different porous media is im-

portant. Gases are highly compressible and an average linear velocity for the column is used. Liquids can be considered incompressible and the average and outlet velocity should be about the same. Supercritical fluids are often assumed to be incompressible for the purpose of calculation, more for convenience than reality, with local velocity changes reflecting changes in density along the column. For packed columns containing porous particles with fluid mobile phases, the flow of mobile phase occurs predominantly through the interstitial spaces between the packing particles and the mobile phase occupying the particle pore volume is largely stagnant. Slow solute diffusion through this stagnant volume of mobile phase is a significant cause of zone broadening for condensed phases. The mobile-phase velocity for a chromatographic system may be determined by dividing the column length by the retention time of an unretained and unexcluded solute from the pore volume (average velocity) or the retention time of an unretained and excluded solute (interstitial velocity).

The mobile-phase flow profile and changes in local velocity are products of the driving force used to induce bulk flow of mobile phase through the separation system. These driving forces can be identified as capillary, pneumatic or electroosmotic forces. Capillary forces are responsible for the transport of the mobile phase in planar chromatography (PC and TLC). These forces are generally weak and result in a mobile-phase velocity that decreases with migration distance from the solvent starting position (**Figure 6**). Capillary forces are incapable of providing a sufficiently high velocity

Figure 6 Relationship between mobile-phase velocity and migration distance for capillary-controlled and forced-flow development in planar chromatography. (Reproduced with permission from Poole CF and Wilson ID (1997) *Journal of Planar Chromatography* 10: 332, copyright © Research Institute for Medicinal Plants).

to minimize zone broadening. This has a number of consequences: zone broadening is largely dominated by diffusion; the useful development length for PC is set by the range of acceptable mobile-phase velocities; separation times are increased; and the separation potential of PC is less than that predicted for a constant and optimum mobile-phase velocity.

Pneumatic transport of the mobile phase is commonly employed in column chromatography. The mobile phase is pressurized externally to the column (a simple high pressure cylinder with regulator in the case of a gas, or a mechanical pump for liquids). The pressure gradient across the column provides the driving force to overcome the resistance to flow pre-

sented by the stationary phase and the rest of the system. In LC, Darcy's law relates the properties of the mobile phase, characteristic features of the column, and the external pressure required to obtain a useful mobile-phase velocity. This law can be stated as:

$$u = \Delta P K_0 d_p^2 / \eta L \quad [1]$$

where u is the mobile phase velocity, ΔP is the pressure drop across the column, K_0 is the column permeability, d_p is the average particle diameter, η is the mobile phase viscosity, and L is the column length. Since a minimum value for u is required for acceptable column performance and separation times, and the available column pressure drop is constrained to an upper limit by material and safety considerations, then there is a finite limit to the range of permissible d_p^2/L values that can be used. Thus a compromise must be accepted between separation time and efficiency, which results in an upper limit to the number of theoretical plates that can be obtained for fast separations or the use of long separation times when very large numbers of theoretical plates are required for a separation.

Bulk liquid flow under electrophoretic conditions occurs by electroosmosis. At the column wall or particle surface (packed columns) an electrical double layer results from the adsorption of ions from the mobile phase or dissociation of surface functional groups. An excess of counterions is present in the double layer in comparison with the bulk liquid and in the presence of an electric field shearing of the solution occurs only within the very thin diffuse part of the double layer, transporting the mobile phase through the column with a nearly perfect plug profile (Figure 7). The velocity of the bulk liquid flow

Figure 7 Flow profile for an open tube and a packed column using pneumatic and electroosmotic driving forces.

is given by:

$$u = \varepsilon \zeta E / 4\pi\eta \quad [2]$$

where ε is the solution dielectric constant, ζ is the zeta potential (potential at the boundary between the charged surface and the start of the diffuse part of the double layer), and E is the electric field strength. Note that there is no explicit dependence on the particle size and column length, which limit the total efficiency of columns when the flow is pneumatically driven. The column length and column internal diameter, however, cannot be treated as independent variables in MEKC and CEC, but are related through Joule heating of the electrolyte and its effect on the mobile-phase flow profile. Heat is generated homogeneously throughout the electrolyte but the temperature variation across the column diameter is parabolic. Radial temperature gradients between the centre of the tube and the column wall cause zone broadening resulting from sample diffusion and solvent density and viscosity differences in the direction of flow.

Zone Broadening

Rate theory attempts to explain the kinetic contribution to zone broadening in column chromatography as the sum of three main contributions: flow anisotropy (eddy diffusion), axial diffusion (longitudinal diffusion), and resistance to mass transfer. Flow anisotropy is illustrated in Figure 8. When a sample band migrates through a packed bed, the individual flow paths must diverge to navigate around the particles such that individual flow streams are of unequal lengths. These variations in flow direction and rate lead to zone broadening that should depend only on the particle size and homogeneity of the column packing. Flow anisotropy can be

Figure 8 Representation of flow anisotropy in a packed column.

minimized by using particles of small diameter with a narrow particle size distribution in columns with a high and homogeneous packing density. For open-tubular columns, flow anisotropy is not a contributing factor since the streamlines have no obstacles in their way to cause disruption of the sample profile.

Axial diffusion is the natural tendency of solute molecules in the mobile phase to redistribute themselves by diffusion from a region of high concentration to one of lower concentration. Its contribution to zone broadening depends on the solute diffusion coefficient in the mobile phase and the column residence time. Diffusion of solute molecules occurs in all directions but only the components in the plane of mobile-phase migration contributes to the peak profile observed in the chromatogram.

Resistance to mass transfer in either the stationary or mobile phases is a consequence of the fact that mass transfer in the chromatographic system is not instantaneous and equilibrium may not be achieved under normal separation conditions. Consequently, the solute concentration profile in the stationary phase is always slightly behind the equilibrium position and the mobile-phase profile is similarly slightly in advance of the equilibrium position (Figure 9). The

resultant peak observed at the column exit is broadened about its zone centre, which is located where it would have been for instantaneous equilibrium, provided that the degree of nonequilibrium is small. Contributions from resistance to mass transfer are rather complicated but depend on the column residence time, mobile-phase velocity, stationary-phase film thickness, the particle size for packed columns, the solute diffusion coefficients in the mobile and stationary phases, and the column internal diameter.

The relationship between zone broadening (column plate height) and the mobile-phase velocity is given by the hyperbolic plot known as a van Deemter curve (Figure 10). The solid line represents the experimentally observed results and the dotted lines the contributions from flow anisotropy (A term), axial diffusion (B/u) and resistance to mass transfer (Cu). In this generic plot we see that there is an optimum velocity at which a particular chromatographic system provides maximum efficiency (a minimum column plate height). The position of this optimum velocity and the general curvature of the plot strongly depend on the characteristics of the chromatographic system, as shown by the values given in Table 1.

Gas Chromatography

Gases of low viscosity with favourable solute diffusivity, such as hydrogen and helium, are commonly used as mobile phases in GC. For these gases the

minimum in the plate height occurs at a high optimum mobile-phase velocity, resulting in efficient and fast separations. At these high mobile-phase velocities the contribution from axial diffusion to the column plate height is minimized. For thin-film columns, resistance to mass transfer in the mobile phase is the main cause of zone broadening, while for thick-film columns resistance to mass transfer in the stationary phase is equally important. Since diffusion in gases is relatively favourable, the column internal diameters required to maintain an acceptable contribution from resistance to mass transfer in the mobile phase offer little difficulty in practice. For supercritical fluids, solute diffusivity is not as favourable as for gases and in the case of liquids must be considered unfavourable. The unfavourable slow optimum mobile-phase velocity in SFC (in practice open-tubular columns are operated at 10 or more times the optimum velocity to obtain an acceptable separation time) requires significantly smaller internal diameter capillary columns than those needed for GC to minimize resistance to mass transfer in the mobile phase. At mobile-phase velocities used in practice the contribution of axial diffusion to the column plate height is negligible compared with the contribution of resistance to mass transfer in the mobile and stationary phases. For fast, high efficiency separations, column internal diameters $< 100 \mu\text{m}$ are required and much smaller diameters are preferred. As densities and solute diffusivity become more liquid-like, column dimensions for reasonable

Table 1 Characteristic values for column parameters related to zone broadening

Parameter	Mobile phase		
	Gas	Supercritical fluid	Liquid
Diffusion coefficient ($\text{m}^2 \text{s}^{-1}$)	10^{-1}	10^{-4} – 10^{-3}	10^{-5}

performance start to approach values similar to those for LC and are not easily attained experimentally. Slow diffusion in liquids means that axial diffusion is generally insignificant but mass transfer in the mobile phase is also reduced, requiring columns of very small internal diameter, preferably < 10 μm , which are impractical for general laboratory use. Packed columns dominate the practice of LC while open-tubular columns are equally dominant in the practice of GC, with both column types used in SFC.

Packed columns in GC are prepared from comparatively coarse particles of a narrow size distribution and coated with a thin homogeneous film of liquid for high performance. The relatively large particle size and short column lengths are dictated by the limited pressure drop employed for column operation. For thin-film columns, resistance to mass transfer in the mobile and stationary phases is the main cause of zone broadening with a contribution from flow anisotropy. For thick-film columns, resistance to mass transfer in the stationary phase tends to dominate. The intrinsic efficiencies of open-tubular columns and packed columns of similar phase ratio are comparable, but because the two column types differ greatly in their relative permeability at a fixed column pressure drop, much longer open-tubular columns can be used. Thus, packed GC columns are

seldom more than 5 m long while columns with lengths from 10 to 100 m are commonly used in open-tubular column GC, resulting in a 100-fold increase in the total number of theoretical plates available. In general, packed columns are used in GC for those applications that are not easily performed by open-tubular columns, for example separations that require a large amount of stationary phase for the analysis of very volatile mixtures, or where stationary phases are incompatible with column fabrication, preparative and process-scale GC, etc.

Liquid Chromatography

The intrinsic efficiency per unit length of packed columns in LC increases as the particle diameter is reduced. It can also be increased by using solvents of low viscosity, which result in smaller contributions to the column plate height from resistance to mass transfer and flow anisotropy. Operation at low mobile-phase velocities compared to GC further minimizes the contributions from resistance to mass transfer in the mobile phase at the expense of longer separation times. The pressure drop required to maintain a constant mobile-phase velocity is proportional to the ratio of the column length to the particle diameter squared. Since the available operating pressure is finite, the column length must be reduced as the

particle diameter is decreased. Consequently, most separations in LC are performed with a total of about 5000–20 000 theoretical plates that is largely independent of the particle size. However, since the retention time at a constant (optimum) mobile-phase velocity is proportional to the column length, this arbitrary fixed number of plates is made available in a shorter time for shorter columns packed with smaller diameter particles. Thus the principal virtue of using particles of a small diameter is that they permit a reduction in the separation time for those separations that do not require a large number of theoretical plates.

Conventional column diameters in analytical LC at 3–5 mm are comparatively large so as to minimize zone broadening from extracolumn effects in earlier instrument designs and have become the *de facto* standard dimensions, even though instrument capabilities have improved over time. Smaller diameter columns have been explored to reduce mobile-phase consumption (which is proportional to the square of the column radius) and to enhance mass detection through reduction in peak volumes, but offer no improvement in the intrinsic column efficiency, except perhaps for columns with a low column diameter-to-particle size ratio. Capillary columns of 0.1 to 0.5 mm internal diameter packed with 3–10 μm particles can be used in relatively long lengths for the separation of complex mixtures, where a large number of theoretical plates is required. Such columns probably minimize the contribution from flow anisotropy while at the same time providing a better mechanism for the dissipation of heat caused by the viscous drag of the mobile phase moving through the packed bed. The operation of these columns is still pressure-limited and separation times an order of magnitude greater than for GC have to be accepted as the price for high efficiency.

The enhancement of intraparticle mass transport is particularly important for the rapid separation of biopolymers, whose diffusion coefficients are perhaps 100-fold smaller than those of low molecular weight compounds in typical mobile phases used in LC. Also, the high surface area porous packings used for small molecules may be too retentive for biopolymers with a significant capacity for multisite interactions. For these compounds short columns packed with 1.5 and 2 μm pellicular or porous particles are used for fast separations. Longer columns containing perfusive particles of a large size with large diameter through-pores to promote convective transport can also be used for fast separations. Perfusive particles are also used for the preparative-scale separation of biopolymers.

Supercritical Fluid Chromatography

In SFC, mobile-phase modification of the stationary phase and its dependence on fluid density, together with the variation of fluid density along the length of the column, result in additional sources of zone broadening that cannot be treated in an exact way. Packed columns used in SFC are identical in type to those used in LC. When separations can be achieved with a modest number of theoretical plates (up to about 80 000), then packed columns provide much faster separations, perhaps up to an order of magnitude, than open-tubular columns, which are generally preferred when very large numbers of theoretical plates are required.

Systems with Electroosmotic Flow

Plug flow in CEC results in a smaller contribution to the plate height from flow anisotropy and transaxial diffusion compared with pressure-driven column liquid chromatography, while contributions to the plate height that are flow-profile-independent are the same. The absence of a pressure drop in electroosmotically driven systems provides the necessary conditions to achieve a larger total number of theoretical plates in CEC in a reasonable time through the use of smaller particles and longer columns (see **Table 2** and **Figure 11**). Under normal operating conditions CEC columns have the potential to provide column plate numbers 5–10 times higher than LC columns. Ultimately the performance in CEC is limited by Joule heating, which causes additional zone broadening and restricts applications of CEC to the use of microcolumns, since columns with a small internal diameter (<100 μm) are required for efficient heat dissipation. The dominant cause of zone broadening in MEKC is axial diffusion, with significant contributions from slow sorption-desorption kinetics between the analyte and micelles and electrophoretic dispersion arising from the polydispersity

Table 2 Achievable theoretical plate numbers in HPLC and CEC

Particle size (μm)	HPLC		CEC	
	Length (cm)	Plates/ column	Length (cm)	Plates/ column
5	5	55 000	50	115 000
3	25	45 000	50	170 000
1.5	10	30 000	50	250 000

Column pressure drop = 400 atm for HPLC and the field strength < 30 kV in CEC for operation at the minimum point in the van Deemter plot.

Figure 11 Separation of aromatic compounds by CEC on a 50 cm \times 50 μ m i.d. fused silica capillary column packed with 1.5 μ m spherical octadecylsiloxane-bonded silica gel with 70% (v/v) acetonitrile buffer as mobile phase, temperature 25°C, and field strength 30 kV.

of micelle sizes. Resistance to mass transfer in the mobile phase is minimized by the capillary dimensions of the column and the small size and homogeneous distribution of the micelles throughout the mobile phase combined with the near-perfect plug flow of the mobile phase. Thermal dispersion, as described for CEC, is an additional potential source of zone

broadening resulting from radial temperature gradients. Separations in MEKC are typically carried out with between 100 000 and 500 000 theoretical plates. Adsorption of solutes on the column wall can greatly reduce the potential column efficiency and experimental conditions should be optimized to minimize these contributions whenever possible.

Planar Chromatography

The consequence of the suboptimal mobile-phase velocity in planar chromatography obtained by capillary-controlled flow is that zone broadening is dominated by diffusion. Since the mobile-phase velocity varies approximately quadratically with migration distance, solutes are forced to migrate through regions of different local efficiency and the plate height for the layer must be expressed by an average value (Figure 12). Each solute in the chromatogram experiences only those theoretical plates over which it migrates, with solutes close to the sample application point experiencing very few theoretical plates and those close to the solvent front experiencing up to an upper limit of about 5000. High performance layers, with a nominal average particle size of about 5 μ m, provide more compact zones than coarser particles, provided that the solvent front migration distance does not exceed about 5–6 cm; beyond this point zone broadening exceeds the rate of zone centre separation. When the development length is optimized the separation performance of conventional layers (average particle size about 10 μ m) is not very

Figure 12 Variation of the average plate height as a function of the solvent front migration distance for conventional and high performance silica gel layers with capillary-controlled and forced-flow development. (Reproduced with permission from Poole CF and Poole SK (1997) *Journal of Chromatography A* 703: 573, copyright © Elsevier Science B.V.)

different from that of the high performance layers; the primary virtue of the latter is that a shorter migration distance is required to achieve a given efficiency, resulting in faster separations and more compact zones that are easier to detect by scanning densitometry. The minimum in the average plate height under capillary-controlled conditions is always greater than the minimum observed for forced-flow development, indicating that under capillary-controlled flow conditions the optimum potential performance is currently never realized in full. Under forced-flow conditions the minimum in the plate height is both higher and moved to a lower velocity compared with values anticipated for a column in LC, (Figure 13). Also, at increasing values of the mobile-phase velocity, the plate height for the layer increases more rapidly than is observed for a column. At the higher mobile-phase velocities obtainable by forced-flow development, resistance to mass transfer is an order of magnitude more significant for layers than for columns. The large value for resistance to mass transfer for the layers may be due to restricted diffusion within the porous particles or is a product of heterogeneous kinetic sorption on the sorbent and the binder added to layers to stabilize their structure. The consequences for forced-flow TLC are that separations will be slower than for columns and fast separations at high flow rates will be much less effi-

Figure 13 Plot of the reduced plate height (H/d_p) against the reduced mobile-phase velocity ($u d_p / D_m$) for a high performance and a conventional TLC layer using forced-flow development superimposed on a curve for an ideal LC column. cient than for columns, although in terms of total efficiency and separation speed the possibilities for forced-flow development are significantly better than those of capillary-controlled separations (Figure 14).

Separation Quality

The general object of a chromatographic separation is to obtain an acceptable separation (resolution)

between all components of interest in a mixture within the shortest possible time. The resolution between two peaks in a chromatogram depends on how well the peak maxima are separated and how wide the two peaks are. This can be expressed numerically by the ratio of the separation of the two peak maxima divided by the average peak widths at their base. Baseline separation of the peaks is achieved at a resolution of about 1.5 but a value of 1.0, representing about 94% peak separation, is taken as an adequate goal for components that are difficult to separate. Resolution is also simply related to the properties of the chromatographic system. For this purpose it is convenient to consider a simple model of a three-component mixture in which the optimum column length is dictated by the number of theoretical plates required to separate the two components that are most difficult to separate, and the total separation time is dictated by the time required for the last peak to elute from the column. The resolution of the two peaks that are most difficult to separate is then related to the column variables by:

$$R_S = (\sqrt{N/2}) \times [(\alpha - 1)/(\alpha + 1)] \times k_{AV}/(1 + k_{AV}) \quad [3]$$

where k_{AV} is the average value of the retention factor for the two peaks, or in an approximate form by:

$$R_S = (\sqrt{N/4}) \times [(\alpha - 1)/\alpha] \times k_2/(1 + k_2) \quad [4]$$

for peaks with approximately equal base widths in which the elution order of the peaks is $k_2 > k_1$.

Column Chromatography

To a reasonable approximation, the three contributions to resolution (efficiency, selectivity and time) can be treated independently and optimized separately. Resolution increases only as the square root of N , so although the influence of efficiency is the most predictable parameter in the resolution equation, it is also the most limited. In practice all separations have to be made in the range $N = 10^3$ – 10^6 (Table 1). For GC this full range is available, so that increasing the column length or, better, reducing the column internal diameter of an open-tubular column at a constant length (separation time is proportional to column length), is often an effective strategy. For LC only a modest number of theoretical plates can be obtained in a reasonable time. In this case the general approach is to use the maximum available value for N and optimize resolution by changing the other variables. SFC is an intermediate case in which the general strategy depends on whether the fluid is more gas-like or liquid-like.

Figure 15 Influence of the separation factor (α) and the retention factor (k) on the resolution of two closely eluting peaks in column chromatography. (Reproduced with permission from Poole CF and Poole SK (1991) *Chromatography Today*, p. 31, copyright © Elsevier Science B.V.)

The separation factor determines the ability of the chromatographic system to differentiate between the two components based on the difference in their thermodynamic interactions with the mobile and stationary phases. When $\alpha = 1$ a separation is impossible but, as can be seen from Figure 15, only a small increase in α above unity is required to improve resolution considerably. At comparatively large values of α , resolution is little influenced by further changes; indeed, separations in which $\alpha > 2$ are easy to achieve. Selectivity optimization is the general approach to improve resolution in LC, where a wide range of mobile and stationary phases are available to choose from and a wide range of different retention mechanisms can be employed. Empirical or statistically based experimental approaches to selectivity optimization are often used because of a lack of formal knowledge of exact retention mechanisms for computer-aided calculations. Although powerful, selectivity optimization in LC can be a time-consuming process. The ease of achieving a separation by selectivity optimization can be

Table 3 Factors affecting resolution in column chromatography

Value of N needed for $R_s = 1$ at $k = 3$ for different values of α		Value of N needed for $R_s = 1$ at different k values for $\alpha = 1.05$ and 1.10		
α	N	k	$\alpha = 1.05$	$\alpha = 1.10$
1.005	1 150 000	0.1	853 780	234 260
1.01	290 000	0.2	254 020	69 700
1.02	74 000	0.5	63 500	17 420
1.05	12 500	1.0	28 220	7 740
1.10	3 400	2.0	15 880	4 360
1.20	1 020	5.0	10 160	2 790
1.50	260	10.0	8 540	2 340
2.00	110	20.0	7 780	2 130

illustrated by the data in Table 3, which indicate the number of theoretical plates required for a separation. These data can be compared to the data in Table 1, which indicates the number of theoretical plates available for different chromatographic systems. This is a clear indication of the need for selectivity optimization in LC and SFC, and the more relaxed constraints for GC.

Resolution will initially increase rapidly with retention, starting at $k = 0$, as shown in Figure 15. By the time k reaches a value around 5, further increases in retention result in only small changes in resolution. The optimum resolution range for most separations occurs for k between 2 and 10. Higher values of k result in long separation times with little concomitant improvement in resolution, but they may be necessary to provide sufficient separation space to contain all the peaks in the chromatogram.

The separation time is given by:

$$t_R = (H/u) \times 16R_s^2 \times [\alpha/(\alpha - 1)^2] \times (k_2 + 1)^3/k_2^2 \quad [5]$$

If the separation time (t_R) is to be minimized, then the acceptable resolution should not be set too high ($R_s = 1$); the separation factor should be maximized for the most difficult pair to separate; the retention factor should be minimized ($k = 1-5$) for the most difficult pair to separate; and the column should be operated at the minimum value for the plate height corresponding to the optimum mobile-phase velocity.

Micellar Electrokinetic Chromatography

The resolution equation for MEKC is identical to eqns [3] and [4] but contains an additional term, $(t_M/t_{MC})/[1 + (t_M/t_{MC})k_1]$, to account for the limited elution range (all solutes must elute between the retention time of an unretained solute, t_M , and a solute

Figure 16 Separation of aromatic compounds by MEKC using a 65 cm (effective length 50 cm) \times 50 μ m i.d. fused silica capillary and a mobile phase containing 30 mmol L⁻¹ sodium dodecyl sulfate and 50 mmol L⁻¹ sodium phosphate/100 mmol L⁻¹ sodium borate buffer (pH = 7) at a field strength of 15 kV. (Reproduced with permission from Terabe S (1989) *Trends in Analytical Chemistry* 8: 129, copyright © Elsevier Science B.V.)

totally retained by the micelles, t_{MC} ; see Figure 16). The intrinsic efficiency of MEKC is much higher than column liquid chromatography, and optimization of the separation factor depends on a different set of parameters (changing surfactant type, use of additives, etc). Large values of the retention factor are unfavourable for obtaining high resolution since the additional term added to the resolution equation tends to zero at high k values. The optimum value of k for maximum resolution is around 0.8–5, corresponding to $(t_M/t_{MC})^{1/2}$. The retention factor is usually optimized by changing the surfactant concentration.

Planar Chromatography

For a single development under capillary-controlled flow conditions the TLC analogue of the general resolution equation for column chromatography can be expressed in approximate form as:

$$R_s = [(N_1 R_{F2})^{1/2}/4] \times [(k_1/k_2) - 1] \times (1 - R_{F2}) \quad [6]$$

where N_1 is the maximum number of theoretical plates available corresponding to the solvent front position. The use of $N_1 R_{F2}$ is only a rough

Figure 17 Variation of the resolution of two closely migrating zones as a function of the R_F value for the faster moving zone. (Reproduced with permission from Poole CF and Poole SK (1991) *Chromatography Today*, p. 669, copyright © Elsevier Science B.V.)

approximation for the number of theoretical plates that a particular zone has migrated across. Relatively small changes in selectivity have enormous impact on the ease of obtaining a given separation in TLC, since the total number of theoretical plates available for a separation is never very large. Separations in TLC are fairly easy when $R_{F2} - R_{F1} > 0.1$ and very difficult or impossible for $R_{F2} - R_{F1} \leq 0.05$ in the region of the optimum R_F value for the separation. Maximum resolution is obtained at an R_F value of about 0.3 and does not change much in the R_F range of 0.2 to 0.5, as can be seen in **Figure 17**. Resolution is zero for compounds that are retained at the origin or migrate with the solvent front.

General Elution Problem

Constant separation conditions, for example isothermal operation in GC and isocratic elution in LC, are unsuitable for separating samples containing components with a wide retention range. Employing average separation conditions will result in a poor separation of early-eluting peaks, poor detectability of late-eluting peaks, and excessively long separation times. In GC there is an approximately exponential relationship between retention time and solute boiling point under isothermal conditions. For mixtures with a boiling point range $> c. 100^\circ\text{C}$ it is impossible to identify a compromise temperature that will provide an acceptable separation. The solution in this case is to use temperature programming, flow programming, or both. Temperature programming is the most common and usually involves a continuous linear increase in temperature with time, although other programme profiles are possible, including segmented programmes incorporating isothermal periods. The reduction in separation time, increase in peak capacity, and nearly constant peak widths obtained are illustrated by the separation in **Figure 18**. The general elution problem in LC is solved using solvent-strength gradients. Here, the composition of the mobile phase is changed as a function of time. Binary or ternary solvent mixtures are commonly used as the mobile phase in which the relative composition of the strong solvent (that solvent with the capability of reducing retention the most) is increased over time. In SFC it is usual to programme the density, mobile-phase composition or temperature as a single factor, but it is also possible for some combination of parameters to be changed simultaneously. The goal remains the same, as indicated by the

Figure 18 Temperature programmed separation of fragrance compounds by GC on a 30 m \times 0.25 mm i.d. fused silica open-tubular column coated with DB-1, film thickness 0.25 μm , helium carrier gas 25 cm s^{-1} and temperature program 40°C (1 min isothermal) then $40\text{--}290^\circ\text{C}$ at 5°C min^{-1} . density- and composition-programmed separation of oligomers in **Figure 19**.

Solvent-strength gradients in TLC are usually discontinuous and achieved through the use of uni-dimensional multiple development. This is accompanied by zone refocusing resulting in a larger zone capacity and easier-to-detect separated zones. All uni-dimensional multiple development techniques employ successive repeated development of the layer in the same direction with removal of the mobile phase between developments. Each time the solvent front traverses the sample zone it compresses the zone in the direction of development because the mobile phase contacts the bottom edge of the sample zone first where the sample molecules then start to move forward before those molecules ahead of the solvent front. Once the solvent front has reached beyond the zone, the refocused zone migrates and is broadened by diffusion in the usual way. When optimized, it is possible to migrate a zone a considerable distance without significant zone broadening beyond that observed for the first development. If the solvent composition is varied for all, or some, of the development steps during multiple development, then solvent strength gradients of different shapes can be produced. With increasing solvent-strength gradients it is usually necessary to scan the separation at a number of intermediate development steps corresponding to the development at which different components of interest are separated, since in later developments these zones may be merged again because of the limited zone capacity in TLC. Alternatively,

Figure 20 Separation of the 3,5-dinitrobenzoyl esters of poly(ethylene glycol) 400 by (A) a single conventional development and (B) by incremental multiple development with a step-wise gradient of methanol, acetonitrile and dichloromethane over 15 developments (Reproduced with permission from Poole CF, Poole SK and Belay MT (1993) *Journal of Planar Chromatography* 6: 438, copyright © Research Institute for Medicinal Plants.)

incremental multiple development can be used with a decreasing solvent-strength gradient. In this case, the first development distance is the shortest and employs the strongest solvent composition, while subsequent developments are longer and employ mobile-phase compositions of decreasing solvent strength. The final development step is the longest and usually corresponds to the maximum useful development length for the layer and employs the weakest mobile phase. In this way sample components migrate in each development until the strength of the mobile phase declines to a level at which some of the sample zones are immobile, while less retained zones continue to be separated in subsequent development steps, affording the separation of the mixture as a single chromatogram (Figure 20). Incremental multiple development with a decreasing solvent-strength gradient is easily automated.

Multidimensional and Multimodal Chromatography

The analysis of complex mixtures requires a very large peak capacity since the probability of peak overlap increases with the number of compounds requiring separation. Multidimensional and multimodal chromatographic systems provide a better route to achieving high peak capacities than is possible with single-column systems. The necessary characteristic of these systems is that the dominant retention mechanism should be different for each dimension. Other uses of multidimensional and multimodal chromatography include trace enrichment, matrix simplification, increased sample throughput, and as an alternative to gradient elution in LC.

Multidimensional column chromatography involves the separation of a sample by using two or more columns in series where the individual columns differ in their capacity and/or selectivity. Multimodal separations involve two or more chromatographic methods in series, for example, the online coupling of LC and GC (LC-GC) or SFC and GC (SFC-GC). Both methods involve the transfer of the whole or part of the eluent from the first column to another via some suitable interface. The function of the interface is to ensure compatibility in terms of flow, solvent strength and column capacity. The design requirements and ease of coupling differ significantly for the different chromatographic modes. Coupling GC-GC, SFC-GC, SFC-SFC, LC-LC, LC-GC and LC-TLC are routine and other combinations such as SFC-TLC, SFC-LC and GC-TLC have been described in the literature. Trace enrich-

ment and sample clean-up on short pre-columns is finding increasing use in the automated determinations of drugs in biological fluids and crop protection agents in water by LC-LC. Figure 21 illustrates the separation of a mixture of deoxyribonucleosides and their 5'-monophosphate esters using LC-LC with an anion exchange column and a reversed-phase column connected in series by a microvolume valve interface. The neutral deoxyribonucleosides are switched as a single peak for separation on the reversed-phase column while the phosphate esters are resolved by the anion exchange column. The separation time remains acceptable since both separations are performed almost simultaneously. TLC-TLC is commonly called two-dimensional TLC and is a widely used qualitative method of analysis. It is very easily performed by placing a sample at the corner of the layer and developing the plate in the normal way, evaporating the solvent, turning the plate through a right angle and developing the plate a second time at 90° to the first development. If adequately optimized this is a very

Figure 21 Separation of the major deoxyribonucleosides and their 5'-monophosphate esters by multidimensional LC-LC. The first column is a strong anion exchange column and the second a reversed-phase column. The unseparated nucleosides, A, are switched to the second column after which the 5'-monophosphate esters, B to D are separated on the IEC column and the parent deoxyribonucleosides, E to H, are separated on the RPC column. (Reproduced with permission from Sagliano N, Hsu SH, Floyd TR, Raglione TV and Hartwick RA (1985) *Journal of Chromatographic Science* 23: 238, copyright © Preston Publication, Inc.)

powerful separation method, but more frequently than not, solvents of different composition are used for the two developments employing retention mechanisms that differ in intensity rather than kind, and the zones are only dispersed around the diagonal between the two development directions and not uniformly over the whole layer.

Mode Selection

Chromatography provides many different approaches for the separation of mixtures. There are many instances where the same mixture can be adequately separated by more than one approach. In this section we will take a mechanistic look at how solutes are separated by the common chromatographic techniques to provide some guidelines for method suitability.

If the only consideration were efficiency and speed, then GC would be the preferred technique. In practice, GC is restricted to thermally stable compounds with a significant vapour pressure at the temperature required for their separation. The upper temperature limit for common GC stationary phases is 200–400°C. Few compounds with a molecular weight greater than 1000 Da have sufficient vapour pressure to be separated in this temperature range, and many low molecular weight compounds are known to be labile at temperatures required for their vaporization. Derivatization techniques extend the scope of GC to otherwise labile compounds by forming thermally stable derivatives, often with increased volatility, and by tagging compounds with specific groups that simplify trace analysis using one of the selective and sensitive group or element-selective detectors available for GC.

Under typical conditions the mobile phase in GC behaves essentially as an ideal gas and does not contribute to selectivity. To vary selectivity either the temperature is changed or a new stationary phase (column) is employed for the separation. Temperature and separation time are closely connected in GC. The range over which temperature can be varied is usually short and will likely provide only a small change in selectivity, but because of the large number of theoretical plates available for a separation in GC, this may be sufficient to provide adequate resolution. Provided that stationary phases that differ in their relative capacity for intermolecular interactions are selected, then larger changes in selectivity can be anticipated by stationary-phase optimization. In modern column technology the most versatile group of stationary phases are the poly(siloxanes), which can be represented by the basic structure $-(R_2SiO)_n-$, in which the type and relative amount of

individual substituents can be varied to create the desired variation in selectivity (R = methyl, phenyl, 3,3,3-trifluoropropyl, cyanoethyl, fluorine-containing alcohol, etc.) Special phases in which R contains a chiral centre or a liquid-crystalline unit are used to separate enantiomers and geometric isomers. Other common stationary phase include hydrocarbons, poly(phenyl ethers), poly(esters) and poly(ethylene glycols), although many of these phases are restricted to packed column applications because of difficulties in either coating or immobilizing them on the walls of fused-silica capillaries, favoured for the manufacture of open-tubular columns. The solvation parameter model provides a reliable systematized approach for selectivity optimization and the prediction of retention in GLC. For GSC the stationary phase is usually silica, alumina, graphitized carbon, organic polymer or zeolite porous particles (packed columns); or a thin layer dispersed over the inner surface of a capillary column with an open passageway down the centre (porous layer open-tubular column, or PLOT column). These materials are used to separate inorganic gases, volatile halocarbon compounds, low molecular weight hydrocarbons and, in particular, geometric and isotopic isomers.

LC and GC should be considered as complementary techniques. Since the only sample requirement for LC is that the sample has reasonable solubility in some solvent suitable for the separation, and since separations by LC are commonly carried out close to room temperature, thermal stability is not generally an issue. The large number of separation mechanisms easily exploited in the liquid phase provides a high level of flexibility for selectivity optimization. In general, many applications of LC can be categorized as those for which GC is unsuited and includes applications to high molecular weight synthetic polymers, biopolymers, ionic compounds and many thermally labile compounds of chemical interest.

Mode selection within LC is quite complicated because of the number of possible separation mechanisms that can be exploited, as illustrated in **Figure 22**. Preliminary information on the molecular weight range of the sample, relative solubility in organic solvents and water, and whether or not the sample is ionic, can be used as a starting point to arrive at a suitable retention mechanism for a separation. The molecular weight cutoff at 2000 indicated in **Figure 22** is quite arbitrary and reflects the fact that size exclusion packings are readily available for the separation of higher molecular weight solutes, although size exclusion is not used exclusively to separate high molecular weight compounds because of its limited peak capacity. Wide-pore packing materials allow polymers with a molecular weight

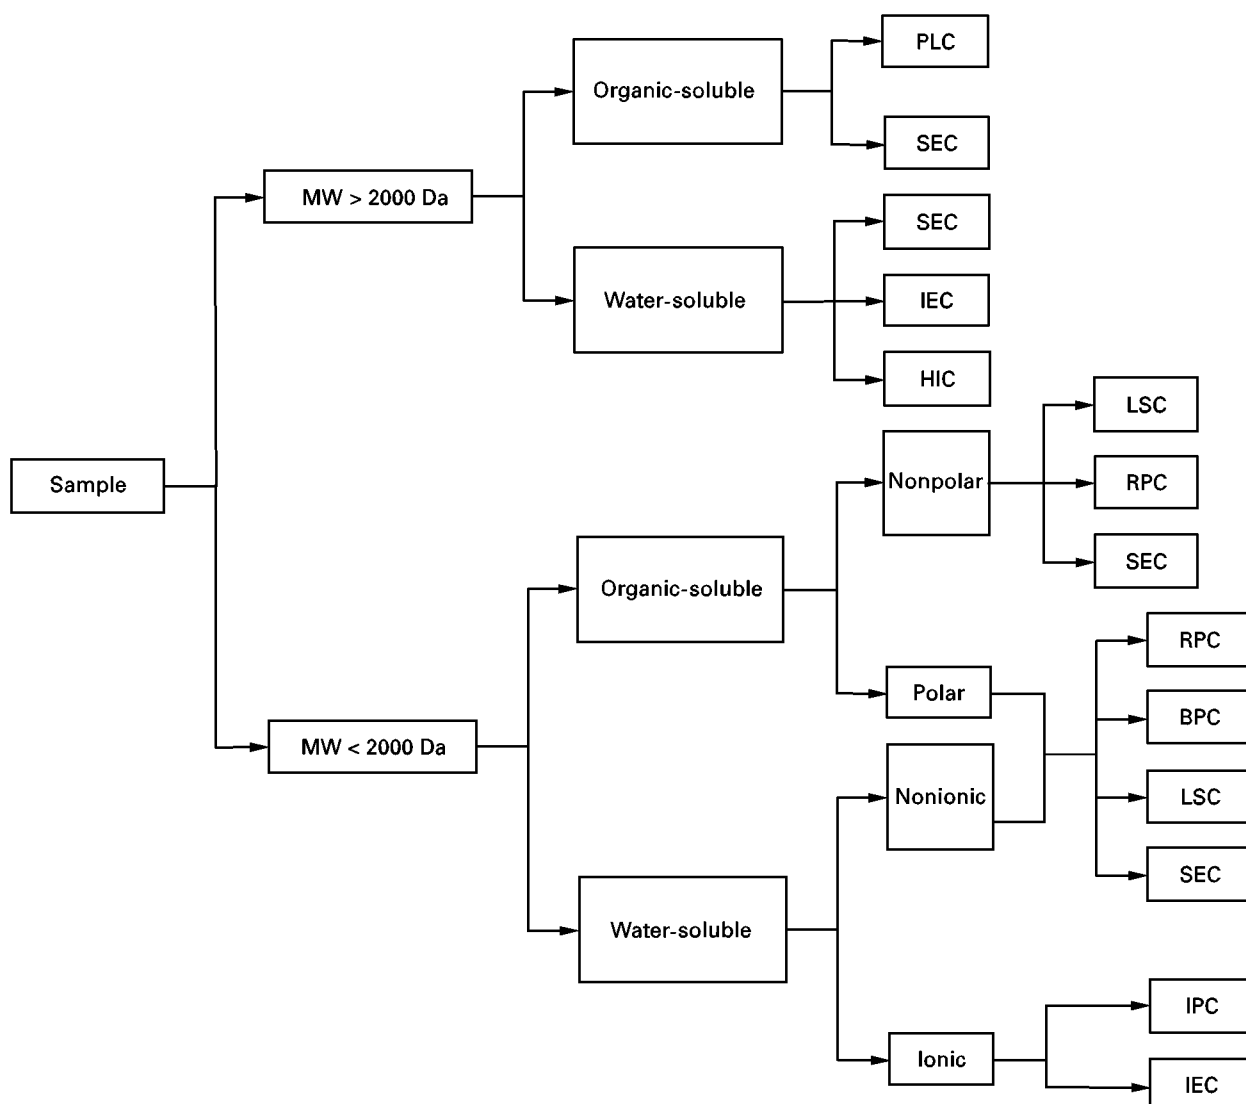

Figure 22 Selection of the separation mechanism in LC based on the criteria of sample molecular weight, solubility and conductivity. (Reproduced with permission from Poole CF and Poole SK (1991) *Chromatography Today*, p. 455, copyright © Elsevier Science B.V.)

exceeding 2000 to be separated by conventional sorption and ion exchange mechanisms.

Liquid-solid chromatography (LSC) is characterized by the use of an inorganic oxide or chemically bonded stationary phase with polar functional groups and a nonaqueous mobile phase consisting of one or more polar organic solvents diluted to the desired solvent strength with a weak solvent, such as hexane. A characteristic of these systems is the formation of an adsorbed layer of mobile-phase molecules at the surface of the stationary phase with a composition that is related to the mobile-phase composition but generally not identical to it. Retention is essentially determined by the balance of interactions the solute experiences in the mobile phase and its competition with mobile-phase molecules for adsorption sites at

the surface of the stationary phase. The position and type of polar functional groups and their availability for interaction with discrete immobile adsorption sites is responsible for selectivity differences when silica or alumina are used as stationary phases. The ability of LSC to separate geometric isomers has been attributed to the lock-key type steric fitting of solute molecules with the discrete adsorption sites on the silica surface.

Reversed-phase liquid chromatography (RPC) is characterized by the use of a stationary phase that is less polar than the mobile phase. A chemically bonded sorbent or a porous polymer could be used as this stationary phase, while for most practical applications the mobile phase contains water as one of its major components. RPC is ideally suited to the

separation of polar molecules that are either insoluble in organic solvents or bind too strongly to inorganic oxide adsorbents for normal elution. RPC employing acidic, low ionic strength eluents is a widely established technique for the purification and characterization of biopolymers. Other favourable attributes include the possibility of simultaneous separation of neutral and ionic solutes; rapid equilibrium between phases facilitating the use of gradient elution; and the manipulation of secondary chemical equilibria in the mobile phase (e.g. ion suppression, ion pair formation, metal complexation and micelle formation) to optimize separation selectivity in addition to variation in solvent type and composition of the mobile phase. A large number of chemically bonded stationary phases of different chain length, polarity and bonding density are available to complement mobile-phase optimization strategies. About 70% of all separations performed in modern LC are by RPC, which gives an indication of its flexibility, applicability and ease of use. The main driving force for retention in RPC is solute size because of the high cohesive energy of the mobile phase compared to the stationary phase, with solute polar interactions, particularly solute hydrogen bond basicity, reducing retention. These findings strongly reflect the properties of water, which is the most cohesive of the solvents normally used in LC, as well as a strong hydrogen bond acid.

Ion exchange chromatography (IEC) is used for the separation of ions or substances easily ionized by manipulation of pH. Stationary phases are characterized as weak or strong ion exchangers based on the extent of ionization of the immobile ionic centres, and as anion or cation exchangers based on the charge type associated with the ionic centres. Thus, sulfonic acid groups are strong, and carboxylic acid groups are weak, cation exchangers. Most of the metal cations in the Periodic Table have been separated by IEC with acids or complexing agents as eluents. In clinical laboratories ion exchange has long been employed as the basis for the routine, automated separation of amino acids and other physiologically important amines involved in metabolic disorders and to sequence the structure of biopolymers. Soft, nondenaturing, ion exchange gels are widely used in the large-scale isolation, purification and separation of peptides, proteins, nucleosides and other biological polymers. Metal-loaded ion exchangers and anion exchange chromatography of complexed carbohydrates are well-established separation techniques in carbohydrate chemistry. The combination of pellicular ion exchange columns of low capacity, low concentration eluents with a high affinity for the ion exchange packing, and universal, online detection with a flow-through conductivity detector revolution-

ized the analysis of inorganic and organic ions in industrial and environmental laboratories. As well as electrostatic interactions, retention in IEC is influenced by hydrophobic sorptive interactions between the sample and stationary phase similar to those in RPC, and size and ionic exclusion effects. Resolution is optimized by choice of the mobile-phase counterion, the ionic strength, pH, temperature, flow rate, and addition of organic modifiers.

In size exclusion chromatography (SEC) retention differences are controlled by the extent to which sample components can diffuse through the pore structure of the stationary phase, as indicated by the ratio of sample molecular dimensions to the distribution of stationary-phase pore size diameters. Since no separation will result under conditions where the sample is completely excluded from the pore volume or can completely permeate the pore volume, the zone capacity of SEC is small compared with that of the other LC techniques. The separation time is predictable for all separations, corresponding (ideally) to a volume of eluent equivalent to the column void volume. No solvent optimization beyond finding a solvent for the sample that is compatible with the stationary phase is required. For synthetic polymers this can result in the use of exotic solvents and high temperatures. SEC is a powerful exploratory method for the separation of unknown samples, since it provides an overall view of sample composition within a predictable time, and is also commonly employed in sample fractionation to isolate components belonging to a defined molecular size range. Analytical separations employ small particles of rigid, polymeric or silica-based gels of controlled pore size to separate samples of different molecular size and to obtain average molecular weights and molecular weight distribution information for polymers.

Fundamentally the retention mechanisms for LC and TLC are identical. TLC is selected over LC when advantage can be taken of the attributes of employing a planar format for the separation. Examples include when a large number of samples requiring minimum sample preparation are to be separated, when post-chromatographic reactions are usually required for detection, or if sample integrity is in question. The use of a disposable stationary phase for TLC allows sample clean-up and separation to be performed simultaneously. Reasons for preferring LC over TLC are its greater separation capacity for mixtures containing more components than can be adequately resolved by TLC; a wider range of stationary phases are available for methods development; a wider selection of detection techniques exist; and automation for unattended operation is more straightforward.

The retention mechanism for MEKC strongly resembles that of RPC with two important differences. Surfactants used to generate the pseudo-stationary phases provide a different type of sorption environment to solvated chemically bonded phases and, therefore, different selectivity. The intrinsic efficiency of MEKC is significantly greater than that of LC and enhances resolution, although the peak capacity is lower owing to the finite migration window for MEKC. A significant number of RPC-type applications are now performed by MEKC, indicating that the method can compete favourably with RPC for some separations. MEKC is inherently a microcolumn technique, providing advantages in coupling to other chromatographic systems and for the analysis of samples only available in small amounts. Disadvantages include sample introduction problems, limited dynamic sample concentration range, and poor limits of detection for trace analysis (because of the very small sample sizes involved). Selectivity optimization is determined largely by the choice of surfactant and the use of mobile- and stationary-phase additives.

Supercritical fluids have solvating properties that are intermediate between those of gases and liquids. In addition, supercritical fluids are compressible so that their density and solvating power can be varied by changing external parameters, such as pressure and temperature. This feature is unique to supercritical fluids and represents a major approach to selectivity optimization. Temperature not only affects density, but may also influence the vapour pressure of low molecular weight solutes, promoting some GC-like character to the retention mechanism. The most common mobile phase is carbon dioxide, a relatively nonpolar fluid. More-polar fluids, such as water, ammonia or methanol, tend to have unfavourable critical constants or are highly corrosive to column or instrument components, limiting their use. Mixed mobile phases can be used to vary selectivity, such as carbon dioxide-methanol mixtures, but miscibility problems and high critical constants for the mixed mobile phases may restrict the range of properties available. SFC can provide faster separations than LC, but it is more restricted than LC in the choice of mobile phases and retention mechanisms to vary selectivity. SFC is compatible with most detection options available for both GC and LC. All practical applications of SFC occur significantly above ambient temperature, which is unsuitable for the separation of some thermally labile compounds and most biopolymers. Supercritical fluids such as carbon dioxide are unable to mask active sites on typical column packings, resulting in unsatisfactory separations of polar compounds owing to adsorption, which pro-

duces unacceptable peak shapes and poor resolution. However, SFC finds applications in many areas where GC and LC are unsatisfactory, for example in the separation of middle molecular weight compounds, low molecular weight synthetic polymers, fats and oils, enantiomers, and organometallic compounds.

Instrumentation

Modern chromatographic methods are instrumental techniques in which the optimal conditions for the separation are set and varied by electromechanical devices controlled by a computer external to the column or layer. Separations are largely automated with important features of the instrumentation being control of the flow and composition of the mobile phase, provision of an inlet system for sample introduction, column temperature control, online detection to monitor the separation, and display and archiving of the results. Instrument requirements differ significantly according to the needs of the method employed. Unattended operation is usually possible by automated sample storage or preparation devices for time-sequenced sample introduction.

Gas Chromatography

For GC a supply of gases in the form of pressurized cylinders is required for the carrier gas and perhaps also for the detector, for operating pneumatic valves, and for providing automatic cool-down by opening the oven door. To minimize contamination, high purity gases are used combined with additional purification devices. Each cylinder is fitted with a two-stage pressure regulator for coarse pressure and flow control. Fine tuning is achieved using metering valves or by electronic pressure control combining electromechanical devices with sensors to compensate automatically for changes in ambient conditions. The column oven is generally a forced air circulation thermostat heated resistively and capable of maintaining a constant temperature or of being programmed over time. The detector and sample inlet are generally thermostated separately in insulated metal blocks heated by cartridge heaters. The most common method of introducing samples into a GC inlet is by means of a microsyringe (pyrolysis, headspace and thermal desorption devices can be considered specialized sample inlets). For packed-column injection a small portion of (liquid) sample is introduced by microsyringe through a silicone septum into a glass liner or the front portion of the column, which is heated and continuously swept by carrier gas. The low sample capacity and carrier gas flow

rates characteristic of narrow-bore open-tubular columns require more sophisticated sample-introduction techniques based on sample splitting or solvent elimination and refocusing mechanisms.

The principal methods of detection are varied, conveniently grouped under the headings of gas-phase ionization devices, bulk physical property detectors, optical detection and electrochemical devices. Further classification is possible based on the nature of the detector response – universal, selective or specific. The flame ionization detector and thermal conductivity detector are examples of (near) universal detectors; the flame photometric detector, thermionic ionization detector and atomic emission detector are element-selective detectors; and the photoionization detector and electron capture detector are structure-selective detectors. GC coupling to mass spectrometry and IR spectroscopy is straightforward and widely utilized for automated structure identification as well as detection. Detection in the gas phase is a favourable process and GC detectors are among the most sensitive and versatile by virtue of the range of mechanisms that can be exploited.

Liquid Chromatography

Modern LC employs columns with small particle sizes and high packing density requiring high pressures for operation at useful mobile-phase velocities. Syringe-type or single- or multiple-head reciprocating piston pumps are commonly used to provide the operating pressures needed in configurations that depend on the design of the solvent-delivery system. A single pump is sufficient for isocratic operation. A single pump and electronically operated proportioning valves can be used for continuous variation of the mobile-phase composition (gradient elution) or, alternatively, independent pumps in parallel (commonly two) are used to pump different solvents into a mixing chamber. Between the pump and sample inlet may be a series of devices (check valves, pulse dampers, mixing chambers, flow controllers, pressure transducers, etc.) that correct or monitor pump output to ensure that a homogeneous, pulseless liquid flow is delivered to the column at a known pressure and volumetric flow rate. These devices may be operated independently of the pump or in a feedback network that continuously updates the pump output. Mobile-phase components are stored in reservoir bottles with provision for solvent degassing, if this is required for normal pump and detector operation. Loop-injection valves situated close to the head of the column are universally used for sample introduction. This allows a known volume of sample to be

withdrawn at ambient conditions, equivalent to the volume of the injection loop, and then inserted into the fully pressurized mobile-phase flow by a simple rotation of the valve to change the mobile-phase flow paths. Although most separations are performed at room temperature, either the column alone or the whole solvent-delivery system may be thermostated to a higher temperature when this is desirable or required for the separation. The separation is monitored continuously on the low pressure side of the column using several bulk physical property, photometric, or electrochemical detectors fitted with microvolume flow cells.

Common detection principles are UV absorbance, fluorescence, refractive index and amperometry. Coupling to MS and IR spectroscopy is becoming more common, as is online coupling to nuclear magnetic resonance (NMR) spectrometers. Detection is a more difficult aspect in the condensed phase and neither the variety nor operating characteristics of LC detectors compare favourably with GC detectors, although they allow a wide range of sample types to be analysed routinely. Special materials are used in the fabrication of biocompatible and corrosion-resistant instruments for the separation of biopolymers and for ion chromatography. Individual pumps can handle solvent delivery requirements over a decade range or so of flow rates. The diversity of column diameters used in modern LC for analysis and preparative-scale applications demands flow rates that vary from a few μL per minute to tens of litres per minute. Consequently, instruments are designed for efficient operation within a particular application range and are not universal with respect to column selection. Furthermore, analytical detectors tend to be designed with sensitivity as the main concern and preparative-scale detectors for capacity, such that the two are generally not interchangeable even when the same detection principle is employed. For preparative-scale work some form of automated sample fraction collection is necessary and economy of operation may dictate incorporation of an integrated mobile-phase recycle feature.

Supercritical Fluid Chromatography

Instrumentation for SFC is a hybrid of components used in GC and LC modified to meet the requirements of operation with a compressible fluid. The mobile phase is typically carbon dioxide (with or without modifier) contained in a pressurized cylinder and delivered to the pump in liquid form. Syringe pumps or cooled reciprocating piston pumps modified for pressure control are commonly used. A high precision

pressure transducer is installed between the pump and sample inlet for programming the inlet pressure or fluid density during the course of a separation. Simultaneous measurement of the column temperature and pressure control allows constant density or density programming under computer control if the appropriate isotherms are known or can be approximated. Two pumps are generally used to generate mobile-phase composition gradients comprising liquid carbon dioxide and an organic solvent. Loop-injection valves similar to LC are the most convenient devices for sample introduction. The column oven is usually a forced air circulation thermostat similar to those used in GC. The full range of flame-based detectors used in GC can be used with only slight reoptimization as well as the main optical detectors used in LC, after modification for high pressure operation. A unique feature of the chromatograph is a restrictor required to maintain constant density along the column and to control the linear velocity of the fluid through the column. Orifice-type restrictors are usually placed between the column and detector for flame-based detectors and back-pressure regulators after the detector flow cell for optical detectors.

MEKC and CEC

MEKC and CEC employ the same instruments as used for capillary electrophoresis with the addition of overpressure capability for the buffer reservoirs when used for CEC. The separation capillary is terminated in two buffer reservoirs containing the high voltage electrodes that provide the electric field to generate the flow of mobile phase. The buffer reservoirs can be moved into place pneumatically and sequenced automatically to introduce a sample vial for sample introduction or a run buffer vial for separation. The column area is thermostated to maintain a constant temperature. A miniaturized optical detector positioned between the buffer reservoirs is commonly used for on-column detection. Some form of interlock mechanism is used to prevent operator exposure to the high voltages, up to 30–50 kV, typically used. A high level of automation is achieved under computer control and unattended operation is generally possible.

Planar Chromatography

The total automation of sample application, chromatogram development and *in situ* quantitation in planar chromatography has proved difficult. Instead the individual procedures are automated, requiring operator intervention to move the layer from one operation to the next. Samples are typically ap-

plied to the layer as spots or narrow bands using low volume dosimeters or spray-on techniques. Application volume, method, location and sample sequence are automated for unattended operation. The chromatogram is obtained by manual development in a number of development chambers of different design, or can be automated such that the conditioning of the layer, the selected solvents for the development, and the development length are preselected and controlled through the use of sensors. For multiple-development techniques the layer can be alternately developed, dried, new solvent introduced and the process repeated with changes in the development length and mobile-phase composition for any or all the programmed development steps. Apparatus for forced-flow development is also available and resembles a liquid chromatograph with the column replaced by the layer sandwiched between a rigid support and a polymeric membrane in an overpressure development chamber to allow external pressure to be used to create the desired mobile-phase velocity.

After development the chromatogram is recorded using scanning or video densitometry. The unique feature compared with detection in column chromatography is that the separation is recorded in space rather than time while in the presence of the stationary phase. The common forms of detection are optical methods based on UV-visible absorption and fluorescence. In mechanical scanning the layer is moved on a translation stage under a slit projecting the image of the monochromatic light source on the layer surface and the light reflected from the surface monitored continuously with a photodiode or similar device. Substances that absorb the light produce a proportional decrease in the intensity of the reflected light that can be related to the amount of sample present (for fluorescence there is a proportionate increase in the amount of light emitted at a wavelength that is longer than the absorbed wavelength). Electronic scanning is not as well developed but involves uniformly illuminating the whole layer and imaging the plate surface onto a video camera, or similar device, to capture and integrate the static image of the absorbing zones.

Conclusion

Many of the important developments in chromatography have already been made, yet the technique continues to evolve by the introduction of new materials that extend the scope of existing methods and through finding new applications. General applications are dominated by the techniques of gas chromatography and column liquid chromatography,

which are the most mature in terms of their evolutionary development, although it is widely recognized that column liquid chromatography still lacks a sensitive and universal detector for general applications. This void may be filled by mass spectrometry, which has made great strides in the last few years towards this goal based on particle-beam interfaces and atmospheric ionization techniques coupled with the development of low cost mass separators. By comparison, thin-layer chromatography and supercritical fluid chromatography have become recognized as techniques with niche applications and are unlikely to supplant gas and column liquid chromatography as the dominant chromatographic methods used in analytical laboratories. The microcolumn techniques of capillary electrophoresis, micellar electrokinetic chromatography, and capillary electrochromatography have quickly established themselves as useful laboratory methods and are likely to become of increasing importance as they complete their evolutionary cycle. In particular, the infant capillary electrochromatography has the potential to replace column liquid chromatography from many of its traditional separation roles, but has yet to reach a state of development to be considered as a routine laboratory technique.

The only thing that is certain about science is uncertainty. Although chromatographic methods are likely to dominate separation science for the first part of the twenty-first century, it would be a foolish person who predicts their form, continuing development, and main applications. Throughout the history of chromatography general approaches have had to adapt to changing needs brought about by dramatic shifts in the focus on different types of applications, and this has a significant impact on the relative importance of the various techniques. However, chromatography should be considered as an holistic

approach to separations, and will be better understood and correctly employed if we abandon the current trend to compartmentalize the technique based on specialization in individual subject areas.

CRYSTALLIZATION

Introduction

Crystallization from solution is a separation technique where a solid phase is separated from a mother liquor. In contrast to other separation processes,

however, the dispersed phase consisting of numerous solid particles also forms the final product, that has to meet the required product specifications. Crystallization can thus also be seen as a technique to obtain solid products, where the crystallization process has to be carefully controlled in order to meet the ever-increasing demands of the customer on particle properties like particle size distribution, crystal shape, degree of agglomeration, caking behaviour and purity. Since the particles must also be easily

separated from the mother liquor, additional demands on filterability and washability can be formulated.

Because of the mostly rigid structure of the solid phase, the formation of solid particles is a rather slow process, and to reach an acceptable production rate large vessels are generally needed. This rigid structure on the other hand impedes the incorporation of foreign substances or solvent molecules, and in only one separation step a pure solid product is obtained.

Crystallization is often used as a generic term for evaporative or cooling crystallization, precipitation and melt crystallization. There are, however, considerable differences between the three types of crystallization as far as the processing method and the corresponding equipment are concerned. In precipitation the drop-out of the solid phase is achieved by mixing two feed streams that are either two reactants or a solvent containing the solute and an antisolvent. The hydrodynamics of the process therefore play a predominant role in precipitation with regard to the properties of the obtained product.

In melt crystallization the potential of crystallization to produce a pure product is mainly utilized, and the solid phase is remolten to obtain the final product. The applications are mainly in the ultrapurification of organic compounds or to produce pure water as a concentration technique.

An upcoming technique in crystallization is supercritical crystallization, mostly with condensed CO₂, because of its benign properties compared to organic solvents. Condensed CO₂ can be used either as a solvent or as an antisolvent, and specifically adapted processes and equipment have been developed for these high pressure crystallization techniques.

Also the crystallization of proteins requires its own dedicated approach, because large, sometimes easily degradable molecules require carefully designed processes.

Because 70% of the products sold by the process industry and the pharmaceutical industry – as bulk products, intermediates, fine chemicals, biochemicals, food additives and pharmaceutical products – are solids, crystallization in its widest definition is the largest separation process after distillation.

Although this chapter will primarily focus on evaporative and cooling crystallization, the energy, mass and population balances treated here as well as the kinetic rate expressions for the physical processes such as nucleation, growth and agglomeration and the characterization of the particles can equally be applied to the other types of crystallization.

Several books on the diverse aspects of crystallization have been published over the last 10 years. These books that can be recommended for a wide overview

in this field contain an abundance of references. The authors of these books are Mersmann (1995), Mullin (1993), Randolph and Larsen (1987), Myerson (1993), Nývlt (1992), Tavare (1995) and Hurlé (1993). Söhnel and Garside (1992) have written a book on precipitation and Arkenbout (1995) a book on melt crystallization.

This article reviews industrial evaporation and cooling crystallization processes. A basic modelling approach is presented which enables the analysis and design of industrial crystallization processes, either by analytical calculations or by making use of modern computational tools.

Crystallization Methods and Supersaturation

Crystallization only occurs when supersaturation is created that acts as the driving force for crystallization. The crystallization method is mainly chosen on the basis of the thermodynamic and physical properties of the compound and the solvent, as well as on the required purity of the product. There are several ways to represent the phase diagram, depending on the mode of crystallization. For evaporative and cooling crystallization a solubility diagram is mostly used, in which the solubility of the compound is expressed as a function of temperature. In precipitation the solubility is always very low, and the solubility product at the operating temperature is needed. In antisolvent precipitation, the solubility diagram mostly has to be determined for the particular three-phase system. In melt cooling crystallization T - x diagrams are used, while for melt pressure crystallization pT - x diagrams are needed.

A decision scheme for the selection of the appropriate crystallization method is presented in **Figure 1**. For a high purity product or when the use of a solvent poses environmental or safety problems, melt crystallization is chosen. A melt temperature lying between 0 and 100°C is preferred, since at higher temperatures many organic compounds become unstable, while at temperatures below 0°C operating the process becomes more difficult, although not impossible. A high viscosity of the melt hampers the operation.

At solubilities below about 1 mass %, the process is designed as a precipitation process to obtain a reasonable production rate. The supersaturation that is generated by the mixing of reactants often reaches high values. Also in antisolvent crystallization, low solubility of the solute and high supersaturation are reached by mixing two solvents.

Finally, for the more easily soluble substances the choice between cooling and evaporative crystallization

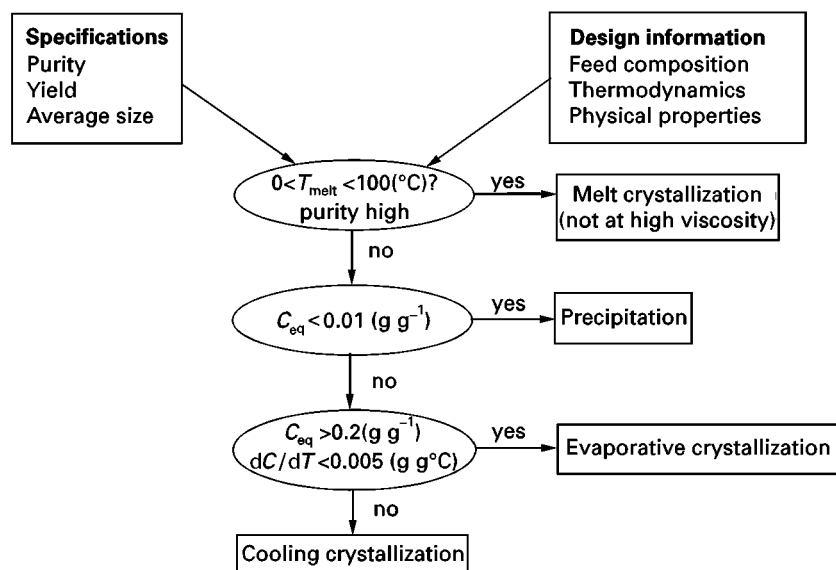

Figure 1 Decision diagram for choosing the method of crystallization.

is made on the basis of the solubility curve, and the prevailing supersaturations are generally low. Especially where water is the solvent, cooling crystallization is more favourable than evaporative crystallization, except for highly soluble substances. Therefore, multi-effect flash evaporation where the vapour is used for heating next crystallizer or the feed stream is frequently applied to reduce the energy costs, if evaporative crystallization is applied.

In cooling crystallization direct cooling, flash cooling or indirect cooling can be applied. Where indirect cooling is used encrustation on the cooling surfaces must be minimized. In flash cooling this problem is largely avoided at the expense of a more complicated installation. Also direct cooling uses an inert cooling medium or refrigerant that is bubbled directly into the solution and evaporates does not suffer from abundant incrustation, but needs recompression of the cooling medium.

So, in these various methods of crystallization, supersaturation is created by cooling, by evaporation of solvent or by a combination of the two in the case of flash evaporation or flash cooling, or by mixing two reactants or solvents. In all these cases the actual concentration is higher than the equilibrium concentration, and a driving force for crystallization is achieved.

From a thermodynamic point of view this driving force is reflected by the difference in chemical potential of the solute in the liquid and in the solid phase at temperature T :

$$\Delta\mu = \mu_L(T) - \mu_S(T) \quad [1]$$

For cooling crystallization from the melt or the solution, eqn [1] can be transformed into:

$$\Delta\mu = \frac{\Delta H_{eq}}{T^*} \cdot \Delta T \quad [2]$$

For melt pressure crystallization:

$$\Delta\mu = \Delta V_{molar} \Delta P = \frac{\Delta\rho}{\rho_{melt}\rho_{solid}} \cdot \Delta P \quad [3]$$

For practical reasons the supersaturation in cooling is mostly indicated by:

$$\Delta T = T - T^* \quad [4]$$

and can also be translated via the solubility curve into a concentration difference:

$$\Delta c = c - c^* \quad [5]$$

Other frequently used expressions are the dimensionless saturation ratio:

$$S = \frac{c}{c^*} \quad [6]$$

or the relative supersaturation:

$$\sigma = \frac{c - c^*}{c^*} = \frac{\Delta c}{c^*} = S - 1 \quad [7]$$

Here c can be expressed by kg solute per kg or m^3 of the solvent or solution, but an expression in kg solute per m^3 solution (=liquid) phase is generally used in mass balances (=mass fraction, w).

For evaporative crystallization, eqn [1] can be transformed into:

$$\Delta\mu = RT \ln\left(\frac{a}{a_{\text{eq}}}\right) = RT \ln\left(\frac{\gamma c}{\gamma_{\text{eq}} c^*}\right) \quad [8]$$

Given the relatively low supersaturations, σ , that often lie between 0.001 and 0.01 with more easily soluble substances, eqn [8] simplifies into:

$$\Delta\mu = RT \frac{\Delta c}{c^*} = RT\sigma \quad [9]$$

For two or more A and B ions in solution that react to form crystal c , the expression for $\Delta\mu$ becomes:

$$\Delta\mu = RT \ln \frac{\prod_i a_i^{\nu_i}}{K_{\text{sp}}} \quad [10]$$

and for stoichiometric solutions equals:

$$\Delta\mu = RT\nu \ln S \approx RT\nu\sigma \quad [11]$$

In practice the supersaturation is often indicated by eqn [5].

For flash cooling or evaporation two terms contribute to the driving force (ΔT and Δc).

For precipitation, no simplifications are allowed, owing to the high supersaturation values ($\sigma \gg 1$), and either eqn [8] or eqn [10] is used. For antisolvent precipitation the value of c depends on the actual concentration of the solute in the original solvent and, like c^* , on the degree of dilution by the antisolvent.

Mass and Heat Balances

Traditional design of an industrial crystallizer is based on only mass and enthalpy balances. The production rate determines to a large extent the dimensions of the crystallizer as well as the energy consumption. It also determines the mode of operation, which means batchwise or continuous, single or multistage operation. In the next section the balance equations are given for an evaporative and for a cooling crystallizer.

Evaporative Crystallizers

Consider an ideally mixed vessel. The composition of the product stream is kept similar to that of the

content of the crystallizer. The volume, V , of the crystallizer is often assumed to be constant in eqns [12–19]. However, by making V and the feed streams time-dependent, dynamic effects can be taken into account, and thus also batch processes. The mass balance is given by:

$$\begin{aligned} \frac{dM_{\text{total}}}{dt} = & \phi_{v,\text{feed}}(\varepsilon_{\text{feed}}\rho_{\text{feed,liquid}} + (1 - \varepsilon_{\text{feed}})\rho_{\text{crystal}}) \\ & - \phi_{v,\text{prod}}(\varepsilon\rho_{\text{liquid}} + (1 - \varepsilon)\rho_{\text{crys}}) - \phi_{v,\text{vapour}}\rho_{\text{vapour}} \end{aligned} \quad [12]$$

The component balances are given by:

$$\begin{aligned} \frac{dM_i}{dt} = & \phi_{v,\text{feed}}\left(\varepsilon_{\text{feed}}\rho_{\text{feed,liquid}}w_{\text{feed,liquid},i} + (1 - \varepsilon_{\text{feed}})\rho_{\text{crystal}}w_{\text{feed,crystal},i}\right) \\ & - \phi_{v,\text{prod}}(\varepsilon\rho_{\text{liquid}}w_{\text{liquid},i} + (1 - \varepsilon)\rho_{\text{crystal}}w_{\text{crystal},i}) \end{aligned} \quad [13]$$

($i = 1, N_{\text{comp}}$)

with:

$$M_i = V(\varepsilon\rho_{\text{liquid}}w_{\text{liquid},i} + (1 - \varepsilon)\rho_{\text{crystal}}w_{\text{crystal},i}) \quad [14]$$

where component $i = 1$ is the main compound to be crystallized, and components $i = 2, 3, \dots, N_{\text{comp}}$ are the impurities present.

The distribution coefficients relate the impurity uptake by the solid and the concentration of the impurity in the liquid phase:

$$k_{\text{distr},i} = \frac{w_{\text{crystal},i}}{w_{\text{liquid},i}} \quad (i = 2, \dots, N_{\text{comp}}) \quad [15]$$

Instead of substituting all component balances into the total mass balance given by eqn [12] to solve the mass balance of the total system, it is more convenient to combine the solvent mass balance together with the component balances:

$$\begin{aligned} \frac{dV\varepsilon\rho_{\text{liquid}}w_{\text{liquid,solvent}}}{dt} = & \phi_{v,\text{feed}}(\varepsilon_{\text{feed}}\rho_{\text{feed,liquid}}w_{\text{feed,solvent}}) \\ & - \phi_{v,\text{prod}}(\varepsilon\rho_{\text{liquid}}w_{\text{liquid,solvent}}) \\ & - \phi_{v,\text{vapour}}\rho_{\text{vapour}} \end{aligned} \quad [16]$$

Finally, the sum of the mass fractions in both the liquid and the solid phase must equal one:

$$w_{\text{liquid,solvent}} + \sum_i w_{\text{liquid},i} = 1 \quad [17]$$

$$\sum_i w_{\text{crystal},i} = 1 \quad [18]$$

The enthalpy balance with the production rate or solids production, P , is given by:

$$\frac{dH}{dt} = \phi_{H,feed} - \phi_{H,prod} - \phi_{H,vapour} + Q_{heat} + P\Delta H_{cr} \quad [19]$$

The total enthalpy and the enthalpy of the streams are defined as:

$$\begin{aligned} H &= V(\varepsilon\rho_{liquid}C_{p,liquid} + (1 - \varepsilon)\rho_{crystal}C_{p,crystal})T \\ \phi_{H,feed} &= \phi_{v,feed}(\varepsilon_{feed}\rho_{feed,liquid}C_{p,liquid} \\ &\quad + (1 - \varepsilon_{feed})\rho_{crystal}C_{p,crystal})T_{feed} \\ \phi_{H,prod} &= \phi_{v,prod}(\varepsilon\rho_{liquid}C_{p,liquid} + (1 - \varepsilon)\rho_{crystal}C_{p,crystal})T \\ \phi_{H,vapour} &= \phi_{v,vapour}(\rho_{vapour}C_{p,vapour}T + \rho_{vapour}\Delta H_{evap}) \end{aligned} \quad [20]$$

The crystal free volume fraction ε should be as low as possible to reduce the crystallizer volume.

The liquid mass fraction $w_{liquid,1}$ of the main component must be determined or can be approximated by the saturation concentration, especially for soluble compounds with a low σ value.

With the production rate, P , as a design parameter, the volumetric product flow rate can be deduced for the chosen ε value from:

$$P = \phi_{v,prod}(1 - \varepsilon)\rho_{crystal} = \phi_{v,prod}M_T \quad [21]$$

From the product flow rate so obtained and the mean residence time that is needed to grow sufficiently large crystals, the necessary suspension volume for the crystallizer can be calculated from:

$$\phi_{v,prod} = \frac{V}{\tau} \quad [22]$$

$$\tau = \frac{L_{mean}}{4G_{mean}} \quad [23]$$

Here, for the desired L_{mean} , a reasonable value must be chosen, that is related to its solubility and the mean growth rate, G_{mean} , can be estimated from a correlation (Mersmann, 1988; Kind and Mersmann 1990) or determined by laboratory experiments.

From the crystallizer suspension volume, V , the needed vapour head, the process streams and the heat duty that has to be accommodated, the crystallizer dimensions can now be determined. Constraints for the design are a height/diameter ratio of about 3 : 2, and a cross-sectional area for evaporation that is large enough to avoid entrainment of liquid droplets

into the condensor. For the design of the heat exchanger see Sinnott (1998).

Cooling Crystallizers

In cooling crystallization the warm feed stream is cooled to the process temperature. In principle the same set of mass and heat balance equations can be used, except that no vapour flow exists. Furthermore, the process temperature cannot freely be chosen, because it is determined for a given production rate, crystal free fraction, ε , residence time, τ and liquid mass fraction, $w_{liquid,1}$. This latter liquid mass fraction of the main component will depend on the process temperature, so a temperature-dependent equation for $w_{liquid,1}$ must be added. The degrees of freedom for the crystallizer design are therefore more limited.

The Population Balance

The Crystal Length-based Population Balance Equation

In crystallization as a separation process, the separability of the particles from the mother liquor by, for example, filtration are of utmost importance, as well as their washability and drying. The efficiency of these processes is directly related to the crystal size distribution (CSD) of the solid, and as soon as the CSD of the solid phase becomes an interesting product specification, the population balance equation (PBE) must be introduced. The PBE describes how the size distribution develops in time as a result of various kinetic processes. The concept of the PBE was introduced to crystallization by Randolph. A general form of the PBE is as follows:

$$\begin{aligned} \frac{\partial(n(L)V)}{\partial t} &= -V\frac{\partial(G_L(L)n(L))}{\partial L} + B(L)V - D(L)V \\ &\quad + \sum_{j=1}^m \phi_{v,in,j}n_{in,j}(L) - \sum_{k=1}^n \phi_{v,out,k}h_{out,k}(L)n(L) \end{aligned} \quad [24]$$

where the amount and the size of the crystals (or particles) are expressed in terms of number density $n(L)$ ($\#/(m^3m)$) and crystal (or particle) length L (m) respectively (Figure 2A).

All the variables in this equation are in principle also time-dependent. For the sake of simplicity, the t dependence is omitted here.

In other representations of the PBE, the amount of particles may also be expressed in terms of volume density $\nu(L)$ ($m^3/(m^3m^1)$) or mass density $m(L)$ ($kg/(m^3m^1)$, where the size is represented by the

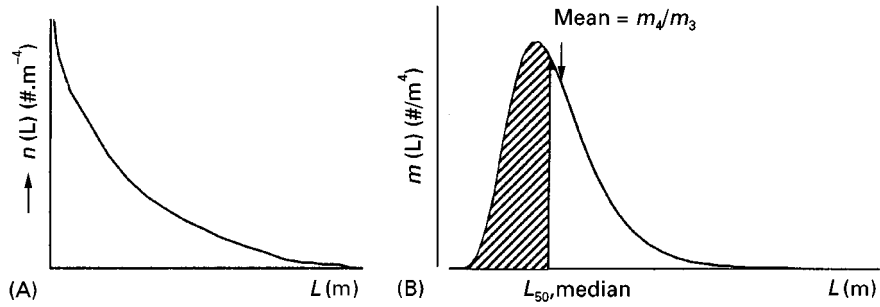

Figure 2 (A) Number and (B) mass distribution of a crystal population.

length L (Figure 2B). Figure 2 also shows two often-used values which characterize the crystal size distribution, the mean crystal size and the volume-based median size (the size at which the integral over the $m(L)$ curve from zero to L_{50} equals half of the integral over the entire curve).

For particle sizes given in terms of volume, the corresponding number density becomes $n(v)$ instead of $n(L)$. The latter representation becomes more convenient if agglomeration of crystals plays an important role.

In eqn [24] V is the suspension volume in the crystallizer with m streams entering and n streams leaving the crystallizer with volumetric flow rates ϕ_v .

$G_L(L)$ is the linear size-dependent growth rate (m s^{-1}), and $B(L)$ and $D(L)$ are birth and death terms

respectively ($\# \text{m}^{-3} \text{m}^{-1}$). Birth and death events can be caused by agglomeration and disruption of earlier agglomerated particles, but also by breakage of crystals and by the birth of small crystals, called nuclei. Breakage of crystals will not happen under normal operating conditions.

The classification function $h(L)$ describes the relation between the CSD in the crystallizer and that on an outlet stream.

The processes on the right-hand side of eqn [24] that lead to the crystal population in a certain size interval, dL , are depicted in Figure 3. In the PBE given by eqn [24] all operation modes are represented. The difference between batch and continuous processes only influences the in- and outflow terms on the right-hand side of the PBE.

Figure 3 Schematic depiction of the processes affecting the CSD. In an infinitesimally small size range from L to $L + dL$, crystals may enter and leave due to growth, aggregation, attrition, breakage and volumetric input and output flow streams.

As the PBE is a partial differential equation with respect to time t and crystal length L , two boundary conditions are needed to solve it analytically:

$$n(0, t) = \frac{B_0}{G_L(0)} \quad [25]$$

$$n(L, 0) = \text{initial distribution} \quad [26]$$

As primary and secondary nucleation typically involve the birth of small crystals, nucleation is often presented as the birth of nuclei at zero size. Instead of a birth term in the PBE for the nucleation event $B(L)$ that happens over a size range $0 \leq L \leq y$, the birth rate B_0 given by the boundary eqn [25] is used. These two are related by:

$$B_0 = \int_0^y B(L) dL \quad [27]$$

For the second boundary condition, a seed population or a population formed by the outgrowth of primary nuclei can be substituted.

Population Balance Equation for Stationary Operation

For continuous crystallization the PBE can be simplified by assuming that:

1. a steady state is reached
2. there is one crystal-free inlet stream
3. nucleation only occurs at zero size and is given by the boundary condition at $L = 0$ (eqn [25])
4. growth is size-independent, $G_L(L) = G_L$
5. the crystallizer volume is constant in t
6. there is no agglomeration or breakage

This results in:

$$VG_L \frac{\partial n(L)}{\partial L} + \sum_{k=1}^n \phi_{v, \text{out}, k} h_{\text{out}, k}(L) n(L) = 0 \quad [28]$$

If the crystallizer content is also well mixed, and there is only one nonclassified outflow, i.e. $h(L) = 1$, this equation becomes:

$$VG_L \frac{\partial n(L)}{\partial L} + \phi_{v, \text{out}} n(L) = 0 \quad [29]$$

Such a crystallizer is named a mixed suspension mixed product removal (MSMPR) crystallizer.

Integration of eqn [29] leads to:

$$n(L) = n(0) \exp\left(-\frac{L}{G_L \tau}\right) \quad [30]$$

By plotting $\ln(n(L))$ versus L , the kinetic growth rate G_L can be derived from the slope of the straight line, and the nucleation rate B_0 from the intercept with the y axis.

The number of process parameters that can be varied for a specific crystallizer in order to shift the CSD and in particular the mean crystal size is usually very limited. Typical process actuators are fines removal and product classification. Their influence on the CSD can be analytically solved by introducing more classified outflow streams, which cause different residence times for the mother liquor and the fine, medium and large crystals in the crystallizer. A generic numeric solution is achieved more easily, as will be addressed later.

Moment Equations for Stationary and In-Stationary Operation

Analytical solutions of the PBE for in-stationary crystallizers hardly exist. By transforming the PBE into a moment form, however, analytical solutions are attained that allow us to describe the dynamical behaviour of crystallizers in terms of the moments of the distribution. The moments are defined as:

$$m_i = \int_0^\infty n(x) x^i dx \quad [31]$$

and the first five moments are related to measurable physical properties of the distribution, as shown in **Table 1**. The shape factors k_a and k_v relate the crystal length to its surface area and volume respectively.

For a continuously operated system with a constant V , a size-independent growth rate, no agglomeration, nucleation at zero size, one crystal-free inlet stream, and a nonclassified product stream, the PBE presented in eqn [24] transforms into:

$$\frac{\partial n(L)}{\partial t} = -G_L \frac{\partial n(L)}{\partial L} - \frac{n(L)}{\tau} \quad [32]$$

Table 1 Physical properties of the moments of the distribution

Property	Symbol	Moment equation
Total number	N_T	m_0
Total length	L_T	m_1
Total surface area	A_T	$k_a m_2$
Total volume	V_T	$k_v m_3$
Total mass	M_T	$\rho k_v m_3$

with similar boundary conditions. This equation can be reduced to a set of ordinary differential equations by means of the moment transformation:

$$\frac{dm_j}{dt} = jG_L m_{j-1} - \frac{m_j}{\tau} + B_0 L_0^j \quad [33]$$

where L_0 , the size of the nuclei, is here zero. Only the first four moment equations ($j = 0-3$) have to be solved to obtain all the information about the lumped properties of the CSD.

Population Balance Equation for Batch Operation

For batch operation, the PBE (eqn [24]) can be simplified by assuming that:

1. the inlet stream is crystal-free
2. nucleation only occurs at zero size, and is reflected by the boundary condition at $L = 0$ (eqn [25])
3. growth is size-independent
4. there is no agglomeration or disruption

This results in:

$$\frac{\partial n(L)V}{\partial t} = -VG_L \frac{\partial n(L)}{\partial L} \quad [34]$$

Since batch operation is inherently ‘in-stationary’, a moment transformation is needed to obtain analytical solutions to the PBE. This leads to

$$d \frac{d(Vm_j)}{dt} = jG_L m_{j-1} V + B_0 L_0^j V \quad [35]$$

where the size of the nuclei, L_0 , is zero. Again ordinary differential equations ($j = 0-3$) have to be solved to attain the lumped properties of the CSD.

To improve the CSD, a controlled cooling or evaporation trajectory can be imposed.

The Crystal Volume-Based Population Balance Equation

When a crystallizing system depends purely on nucleation and growth processes, it is favourable to use a PBE with length as the crystal size co-ordinate. For kinetic processes where the volume of particles are combined or split up, like in agglomeration and disruption, a PBE with the particle volume as crystal size coordinate is preferred. This leads to:

$$\begin{aligned} \frac{\partial(n(v)V)}{\partial t} = & -V \frac{\partial(G_v(v)n(v))}{\partial v} + B(v)V - D(v)V \\ & + \sum_{j=1}^m \phi_{v,in,j} n_{in,j}(v) - \sum_{k=1}^n \phi_{v,out,k} b_{out,k}(v)n(v) \end{aligned} \quad [36]$$

A volumetric growth rate is then required. Crystal growth rates are, however, available in length-based rates, so $G(v)$ has to be calculated from:

$$G_v(v) = \frac{dv}{dL} G_L = 3k_v L^2 G_L \quad [37]$$

This expression prohibits the introduction of zero-sized nuclei as a boundary condition, and nucleation has to be modelled as birth within a certain size interval.

The number of particles in a certain size interval must be the same, regardless of whether the bounds of that interval are expressed in terms of length of volume. This implies that:

$$n(L) dL = n(v) dv \quad [38]$$

and, after some rewriting, the following transformation equations:

$$n(L) = 3k_v L^2 n(v)$$

$$n(v) = \frac{1}{3\sqrt[3]{k_v v^2}} n(L) \quad [39]$$

Agglomeration and Disruption

To solve the PBE where there is agglomeration and disruption of earlier agglomerated particles, the birth and death terms for these processes must be derived.

The rate of agglomeration, r , is given by:

$$r(v_1, v_2) = \beta(v_1, v_2, \sigma, \varepsilon) n(v_1) n(v_2) \quad [40]$$

The rate constant, β , commonly called the agglomeration kernel, depends on the particle sizes v_1 and v_2 , the supersaturation σ and the turbulence level, represented by the power input ε . The birth and death terms associated with the agglomeration of two particles, resulting in the birth of a new one and the death of the original two, are:

$$B(v) = \frac{1}{2} \int_0^v \beta(u, v-u) n(u) n(v-u) du \quad [41]$$

$$D(v) = n(v) \int_0^\infty \beta(u, v) n(u) du \quad [42]$$

The factor $\frac{1}{2}$ is needed to avoid double-counting, since the integral takes each interaction twice. The dependency of β on σ and ε has been omitted here for notation simplicity.

There is also disruption of earlier agglomerated particles with a corresponding disruption rate. This disruption process of earlier agglomerated particles

can be described in the PBE by an additional death term for the disrupted particles, and an additional birth term for the newly formed particles:

$$D(v) = S(v, \varepsilon) \cdot n(v) \quad [43]$$

$$B(v) = \int_v^\infty b(v, u) S(u, \varepsilon) n(u) du \quad [44]$$

where $S(v)$ is a selection function that describes the rate at which particles fall apart, and b is a breakage function that describes how many particles of size v are formed on disruption of a particle of size u .

Often, the disruption terms are loaded into the agglomeration kernel β , which then represents the effective agglomeration kernel. In that case terms expressed by the eqns [43] and [44] can be left out and only eqns [41] and [42] are needed for substitution in the PBE. The main disadvantage of this lumped description of the whole agglomeration process is that prediction of the agglomeration behaviour for different hydrodynamic conditions (and thus for different scales and geometries) becomes virtually impossible because β and σ have a different dependency on ε .

The PBE with agglomeration and disruption terms can rarely be solved analytically. A moment transformation is again required with the moments defined as:

$$m_i = \int_0^\infty n(v) v^i dv \quad [45]$$

where v represents crystal size volume v . The zero moment is again the total number of particles, but the first moment of the volume-based CSD already equals the third moment of the length-based CSD.

Substitution of the above expressions into the PBE (eqn [36]) for a system with agglomeration and growth and no nucleation, with a constant crystallizer volume, only one crystal-free inlet stream and a nonclassified product stream, results after a moment transformation in:

$$\frac{dm_i}{dt} = -\frac{m_i}{\tau} + jG_v m_{i-1} + \overline{B_{\text{aggl},j}} - \overline{D_{\text{aggl},j}} \quad [46]$$

where the moment forms of B and D due to agglomeration are defined as:

$$\overline{B_{\text{aggl},j}} = \int_0^\infty v^j B dv \quad [47]$$

$$\overline{D_{\text{aggl},j}} = \int_0^\infty v^j D dv \quad [48]$$

A solution is only obtained for a size-independent kernel β_0 . For a batch-agglomerating system (without growth), only solutions for m_0 and m_1 (which is equal to the m_3 in size coordinates) are obtained:

$$\frac{dm_0}{dt} = -\frac{1}{2}\beta_0 m_0^2 \quad [49]$$

$$\frac{dm_1}{dt} = 0 \quad [50]$$

The numerical solution of the population balance for cases where nucleation, growth and agglomeration is present often imposes a problem, because no analytical solution exists and the generation of numerical solutions is not easy. It is essential to divide the size axis into proper size intervals to obtain reliable results and to transform the population balance, a partial differential equation, into a set of ordinary differential equations. Hounslow *et al.* presented a numerical scheme based on a geometrical discretization of the size axis in which for each size interval the ratio between the upper and lower boundary r is exactly equal to $\sqrt[3]{2}$. Although accurate results are obtained in the absence of crystal growth and nucleation, the method is in general not accurate enough in the presence of these crystallization phenomena and gives rise to an overestimation of the higher moments. An improved finite-element technique has been introduced to solve the steady-state solution of the population balance for nucleation, growth and agglomeration.

Kinetic Expressions

In order to solve the population balance equation, kinetic expressions are needed to represent the physical processes that take place in the crystallizer, such as nucleation, growth and agglomeration. Their mechanisms and the corresponding equations will be treated here.

Nucleation

Two different nucleation mechanisms can be distinguished: primary and secondary nucleation.

Primary nucleation is new phase formation from a clear liquid or solution. It can be subdivided into homogeneous and heterogeneous nucleation. In the latter case a foreign substrate of tiny invisible particles, e.g. dust or dirt particles, is present in the solution on which nucleation starts. In homogeneous nucleation such a substrate is absent and nuclei are formed by statistical fluctuations of solute entities that cluster together.

Secondary nucleation is the breeding of nuclei from crystals of the crystallizing material that are already present in the solution. These nuclei are in general attrition fragments, and result from collisions of the larger crystals with the hardware of the crystallizer, in particular with the blades of impellers and pumps. At high solid densities in the crystallizer collisions between the larger crystals can create fragments that act as secondary nuclei.

During the start-up phase of evaporative or cooling crystallization of moderately to very soluble compounds, primary nucleation takes place. After their outgrowth to larger crystals, secondary nucleation takes over, and becomes the most important source of nuclei at low supersaturation values. For precipitation of slightly soluble compounds the process generally remains dominated by primary nucleation for two reasons. Supersaturation remains high enough, especially at the inlet points of the feed streams, to produce primary nuclei, and the often agglomerated crystals remain too small to be prone to attrition.

Homogeneous primary nucleation Local fluctuations in concentration induce the formation of numerous clusters that can fall apart again. In under- or just saturated solutions, cluster formation and cluster decay are in equilibrium; it is a reversible process. In supersaturated solutions, however, clusters of a critical size are formed that either fall apart or grow out. In the classical nucleation theory of Volmer, Becker and Döring, these clusters are formed by the attachment and detachment of single solute entities. Although clusters can also grow by the collision of clusters, their concentration is always so much lower than that of single solute entities that this process of cluster enlargement can be ignored.

The critical size of a cluster that is represented by its critical radius, r^* , is given by:

$$r^* = 2\gamma \frac{V_{\text{molar}}}{\Delta\mu} \quad [51]$$

and is thus related to the supersaturation via $\Delta\mu$, and to the interfacial tension γ .

For the homogeneous nucleation rate, J_{homo} ($\#m^{-3}$), the following equation can be derived after some simplifications:

$$J_{\text{homo}} = AS \exp\left(\frac{16\pi\gamma^3 V_{\text{molar}}^2}{3k^3 T^3 (\ln S)^2}\right) \quad [52]$$

In this Arrhenius type of expression, changes in the supersaturation ratio S in the pre-exponential factors $A \cdot S$ are of minor influence compared to changes in S in the exponential term. Various authors use dif-

ferent expressions for A and this can cause considerable differences in the attained values of J (Merzmann, 1995; Söhnel and Garside, 1992; Kashchiev, 2000).

Heterogeneous primary nucleation The occurrence of homogeneous nucleation is rare, in practice since nucleation on a foreign substrate will substantially reduce the nucleation barrier. For this type of nucleation, a similar rate equation can be used:

$$J_{\text{hetero}} = A_{\text{hetero}} S \exp\left(\frac{16\pi\gamma^3 V_{\text{molar}}^2}{3k^3 T^3 (\ln S)^2}\right) \quad [53]$$

where the interfacial tension γ is replaced by a much lower γ_{eff} . Although A_{hetero} is lower than A , the effect of the exponential term dominates up to very high supersaturation values, that are rarely met in practice (Figure 4).

Secondary nucleation The classic expression for the secondary nucleation rate in a suspension of growing crystals, B_0 , is the empirical power law, based on three experimentally accessible parameters that were recognized already early on to be important:

$$B_0 = k_N G^i N^h M_T^j \quad [54]$$

Since the growth rate is directly related to the supersaturation σ , and the rotational speed to the power input, the power law can also be written as:

$$B_0 = k_N^1 \sigma^b \varepsilon^k M_T^j \quad [55]$$

Frequently measured values for b , k and j under steady-state conditions are $1 < b < 3$, $0.6 < k < 0.7$ and $j = 1$ or 2 . For nucleation dominated by crystal-impeller collisions $j = 2$, while for nucleation ruled by crystal-crystal collisions, $j = 2$.

Figure 4 Nucleation rate as a function of the supersaturation ($\Delta\mu$). J_{homo} and J_{hetero} , homogeneous and heterogeneous nucleation rate; B_0 , secondary nucleation rate.

Also the crystallizer geometry-like type of stirrers or pumps, and number of blades, as well as the scale of operation influence the attrition rate of the crystals. These effects were supposed to be included in k_N of k_N^1 , that could only be established experimentally. The power law with its four parameters, used together with other kinetic parameters (e.g. those related to the growth of the crystals) seems to be perfectly adequate to describe the steady-state median crystal size in continuous crystallization processes.

The power law, however, fails to describe the dynamics of a crystallization process. If, for example, the median crystal size is plotted versus time from immediately after the start-up, often an oscillating behaviour is observed that dampens out until finally a steady-state value is reached (Figure 5). This oscillating behaviour can be explained by the observation that only crystals above a certain size breed secondary nuclei by attrition. The first nuclei are created by primary nucleation and grow out, which causes the supersaturation to decrease. When the mean size has reached its first peak, more of the larger crystals are withdrawn with the product than are grown into the larger crystal sizes by outgrowth of secondary nuclei. This happens because at the early stages no large crystals are available for breeding.

Some groups have tried to account for this phenomenon by adding a target efficiency to the power law that is a function of the crystal size. One author, Eek, allowed only crystals above a certain size to breed. This improved the simulations, although none of them was fully successful.

An attrition function for the crystals, was introduced by O'Meadhra based on the approach of Mersmann. He distributed the attrited volume over the small crystal sizes. In this way a birth function $B(L)$ was calculated from the volumetric attrition rate. A disadvantage of this modelling, in common with the power law, is that it has no predictive value, since

the attrition function also must be determined experimentally for the particular crystallizer.

Gahn and Mersmann were the first to derive a secondary nucleation rate model based on physical attrition properties. Their approach comprises three consecutive steps and calculates the secondary nucleation rate of crystals that collide with the blades of an impeller.

1. A simplified flow pattern based on geometric considerations as presented by Ploss *et al.* is used to calculate the impact velocity and the chance of crystals from size class i to collide with an impeller segment j .
2. Subsequently a model was developed to calculate the volume of attrition fragments produced during a single collision of a crystal corner represented by a cone, and a hard flat surface of the impeller. The model relates the attrited volume of crystal i and segment j to the impact energy of the crystal collision via its relevant mechanical properties, such as the Vickers hardness, the fracture resistance of the substance and the shear modulus. The model assumes that the circulation time is sufficient to heal the damaged crystal corner before a subsequent collision of the same corner takes place. This assumption is often not valid for crystallizers up to 100 L. A minimum impact energy required to cause fracture can also be derived, and thus the minimum crystal size for a given velocity profile is prone to attrition. The model also provides a normalized number density function of the fragments formed at each collision of crystal i with impeller segment j . In general, the size distribution of fragments lies in the range from 2 to 100 μm .
3. In the third step the rate of secondary nucleation is linked to the rate of formation of attrition fragments. The amount of stress remaining in the fragments limits the number that grows into the population, because stress increases their chemical potential. Their real saturation concentration c^* becomes:

$$c_{\text{real}}^* = c^* \exp\left(\frac{\Gamma_K}{KTL_{\text{fragment}}}\right) \quad [56]$$

The stress content of the fragments is directly related to their length, and the value of Γ_K has to be determined experimentally, for example from experiments where the fines of a crystallizer are withdrawn, and allowed to grow out in a growth cell.

The formed fragments with size L_{fragment} can now be distributed with their respective length and stress content. A number of fragments will dissolve, and the

Figure 5 Dynamic behaviour of the CSD. Continuous line, measured; dashed line, modelled with the power law.

rest will grow into the population with a size-dependent growth rate.

This model does not deliver a secondary nucleation rate, B_0 , with nuclei born at zero size or a birth term, $B(L)$, for the distribution of secondary nuclei, but calculates from the number of collisions, and from the surviving fragments per collision, the number of new developing crystals. Since for this calculation an initial CSD is needed, iteration loops are always needed if this nucleation model is used as a predictive tool for secondary nucleation.

Both this model and that of O'Meadhra are able to describe the dynamic behaviour of crystallization processes.

Crystal Growth

Definitions of growth rate The growth rates of the crystallographically different faces ($h k l$) of a crystal can vary considerably. The growth rates of the crystal faces determine the shape of the crystal and, together with the growth mechanisms, also the crystal surface structure.

The growth rate of a particular crystal face ($h k l$) is mostly defined by its linear growth rate R_{lin} ($m s^{-1}$), which refers to the growth rate of that face along the normal direction. An overall linear growth rate \bar{R}_{lin} averaged over all different ($h k l$) faces can be defined in several ways. One definition which is often used relates \bar{R}_{lin} to the increase of the crystal mass in time:

$$\frac{1}{A} \frac{dm}{dt} = \frac{\rho k_v}{k_a L^2} \frac{dL^3}{dt} = 3 \frac{k_v}{k_a} \rho G_L = 6 \frac{k_v}{k_a} \rho \bar{R}_{lin} \quad [57]$$

For spheres and cubes (or for crystals where L is based on the diameter of a sphere with the same volume), $k_a/k_v = 6$, and:

$$\frac{1}{A} \frac{dm}{dt} = \frac{1}{2} \rho G_L = \rho \bar{R}_{lin} \quad [58]$$

Figure 6 Diffusion of a growth unit towards and integration into the crystal surface layer.

Note that $G = dL/dt = 2 \bar{R}_{lin}$ for substitution of the linear rate equations in the population balance equation.

Crystal growth mechanisms For growth from solution the crystal growth processes can be roughly divided into two steps (Figure 6):

1. (volume) diffusion of growth units towards the crystal-solution interface
2. subsequent integration of these growth units into the crystal surface

The concentration profile perpendicular to the crystal surface is given in Figure 7, where the concentrations in the bulk at the crystal-solution interface and the equilibrium concentration at the growth site are indicated by c_b , c_i and c^* respectively.

For very soluble compounds, the growth rate is only limited by diffusion through the stagnant layer with thickness δ at the interface, with $c_b - c^*$ as the driving force for diffusion. For poorly soluble compounds the surface integration step is growth-limiting, and the driving force for the integration equals $c_b - c^*$. For most compounds, however, both steps must be taken into account. For growth from the melt the transport of the heat of crystallization becomes a third rate-limiting step. This is also the case for very concentrated solutions. In the following, first the surface integration and volume diffusion growth mechanisms and the related growth rate

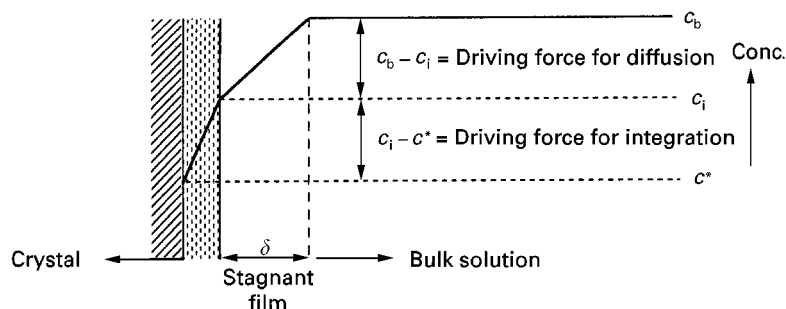

Figure 7 Concentration profile perpendicular to the crystal surface during growth.

expressions will be given, as well as the growth rate expressions for a combination of both steps. The expressions for heat transfer-controlled growth and for simultaneous heat and mass transfer will not be discussed here.

Surface integration controlled growth

Rough surfaces The structure of a growing surface at a molecular level is influenced by several factors: first, by the binding energies between the atoms, ions or molecules in the crystal surface layer. Also the solvent, temperature and driving force can play an important role. Depending on these factors, surfaces can become roughened. For a given compound and a selected solvent, either thermal or kinetic roughening may occur.

Each crystal face has a critical temperature above which the surface becomes rough. For ionic compounds these temperatures are very high, and always above the normal operating conditions. For organic compounds, however, roughening temperatures can even be close to room temperature, as with paraffin crystals growing from hexane. For rough growth the crystal faces tend to become rounded, especially at the edges, and nicely faceted crystals are no longer formed.

Kinetic roughening is caused by growth at too high supersaturation, and also happens for ionic substances. Rough growth always affects the crystal quality in a negative way, in particular the crystal purity, since impurities or solvent molecules are more easily incorporated.

It is not surprising that for rough growth the linear growth rate depends linearly on the supersaturation, because all surface sites can act as growth sites, and the rate constant k_r is proportional to the solubility of the compound. The solubility reflects the number of growth units that potentially impinges on the crystal surface, and thus contributes to its growth. The linear growth rate is given by:

$$R_{\text{lin}} = k_r \sigma \quad [59]$$

Smooth surfaces For growth of smooth crystal faces, as normally happens under moderate operating conditions, an orderly deposition of subsequent growth layers is needed. This can be realized by the propagation of growth steps along the crystal surface (Figure 6). Two sources can be identified for the generation of steps, and the two mechanisms of layered crystal growth are named after these sources: the 'birth and spread' or two-dimensional (2D) nucleation and growth model or the spiral growth model.

In the birth and spread model the steps are generated by the formation of 2D nuclei on the crystal surface that grow into islands by spreading laterally along the crystal surface. New nuclei can be formed on the original surface as well as on top of the already growing island. 2D nuclei can only be formed if the supersaturation is high enough to overcome the 2D nucleation barrier. The linear growth rate is given by:

$$R_{\text{lin}} = k_r (S - 1)^{2/3} S^{1/3} \exp\left(-\frac{B_{2D}}{3 \ln S}\right) \quad [60]$$

where $S = \sigma + 1$.

At low supersaturations, where 2D nuclei are not yet formed, screw dislocations that are present as lattice defects in the crystals and emerge on the crystal surface will act as step sources. The steps will curve around the defect emerging point, and spiral hillocks are formed.

The linear growth rate, also known as the parabolic growth law, equals:

$$R_{\text{lin}} = k_r \sigma^2 \quad [61]$$

In both eqns [60] and [61] k_r is directly proportional to the solubility of the compound. This solubility dependence is clearly seen in plots of the growth rates and the mean crystal sizes of many salts versus the supersaturation, as given by Mersmann. So, at the low supersaturations generally prevailing in evaporative and cooling crystallization, the surface integration growth step mostly obeys the parabolic law. At higher supersaturations, 2D nucleation and growth take over. If, at very high supersaturations, the size of the 2D nuclei approaches that of one growth unit, rough growth occurs (Figure 8).

Volume diffusion controlled growth Because diffusion through the stagnant boundary layer at the crystal surface is the rate-limiting step, this

Figure 8 Growth curves for spiral, birth and spread (B&S) and rough growth.

growth model is also called the diffusion layer model. Even for rather concentrated solutions the simplified Fick's law can be applied, and the increase in crystal mass is given by:

$$\frac{dm}{dt} = \frac{D}{\delta} A(c_b - c^*) = k_d A(c_b - c^*) \quad [62]$$

The mass transfer coefficient k_d follows in its simplest form from $Sh = k_d L/D$, where for Sh several correlations provided in literature can be used. The values for Sh generally lie between 2 and 10. For concentrated solutions the Maxwell–Stefan equation is used

$$\frac{dm}{dt} = \frac{k_d}{(1-w)} A(c_b - c^*) \quad [63]$$

with w = mass fraction of the solute.

So, for most cases the linear growth rate is given by:

$$\bar{R}_{lin} = \frac{k_a k_d}{6k_v \rho} c^* \sigma \quad [64]$$

The dependency of \bar{R}_{lin} on σ is first order, and \bar{R}_{lin} is directly related to the solubility. It always limits the maximal growth rate by which a crystal can grow at a given supersaturation in Figure 8.

Volume diffusion and surface integration controlled growth For combined volume diffusion and rough growth as growth rate-determining steps, the growth process can be described by:

$$\frac{1}{A} \frac{dm}{dt} = \frac{k_d k_r}{k_d + k_r} (c_b - c^*) \quad [65]$$

while for combined volume diffusion and spiral growth surface integration the growth rate becomes:

$$\frac{1}{A} \frac{dm}{dt} = k_d(c_b - c^*) + \frac{k_d^2}{2k_r} - \left[\frac{k_d^4}{4k_r^2} + \frac{k_d^3(c_b - c^*)}{k_r} \right]^{1/2} \quad [66]$$

With eqn [57] either \bar{R}_{lin} or G can be calculated.

The temperature dependence of k_r and k_d is given by an Arrhenius-type equation, where the corresponding Arrhenius activation energies are typically of the order of 40–60 kJ mol⁻¹ for surface integration and 10–20 kJ mol⁻¹ for the volume diffusion step.

For easily soluble compounds generally linear growth rates of 10⁻⁷ m s⁻¹ are permissible in order to

obtain smoothly grown crystals at σ values of 0.001 to 0.01, while for slightly soluble substances growth rates of 10⁻⁹ to 10⁻⁸ m s⁻¹ are commonly encountered at σ values of 10–100. Their corresponding mean sizes vary from 600 μ m to 10 μ m respectively.

Growth rate dispersion Small crystals, regardless whether they are born by primary or secondary nucleation, grow slower than their parent crystals. This is attributed to a certain content of stress in the small crystals. During the growth of the nuclei, the outer layers of the crystals lose some of the stress – a process called healing. Although the stress content of individual small crystals of the same size can differ, and thus their growth rate – a phenomenon named growth rate dispersion – the overall effect of stress on the growth rate of a large number of small crystals can equally be described by a size-dependent growth function. The equilibrium concentration then becomes a size-dependent function analogous to eqn [56].

$$G(L) = kg \left(\sigma - \frac{W_i(L)}{kT} \right)^g \quad [67]$$

where $W_i(L) = \Gamma_k/L_{fragment}$ and $g = 1$ for volume diffusion-dominated growth, and 2 for spiral growth. The value of Γ_k is, as mentioned before, a fitting parameter that has to be determined experimentally.

Dissolution of Crystals

Only at very low undersaturations or for extremely insoluble substances such as BaSO₄, the dissolution process proceeds by the disappearance of subsequent layers, and a smooth surface is maintained. Normally surface disintegration occurs at the crystal edges and at etch pits, and the surface becomes easily roughened. So the dissolution rate is either given by an expression where only volume diffusion is rate controlling:

$$-\frac{1}{A} \frac{dm}{dt} = k_d(c^* - c_b) \quad [68]$$

or by a combined volume diffusion and surface disintegration rate, as given by eqn [65] and, more rarely, by eqn [66], but now with a negative value for the change in mass, and a decreasing A .

Agglomeration

The agglomeration process consists of the transportation and collision of particles, and the attachment of the particles, followed by either disruption or cemen-

Table 2 Predominant agglomeration models for the possible transport mechanism as a function of particle size L and the Kolmogorov length scale η

Transport mechanism	Particle size L	Collision mechanism
Brownian motion	$L < 0.5 \mu\text{m}$	Perikinetic
Laminar flow	$L < 6 \eta$	Orthokinetic
Laminar flow	$L > 25 \eta$	Inertial
Turbulent flow	$L < 6 \eta$	Orthokinetic
Turbulent flow	$L > 25 \eta$	Inertial
Relative particle settling	$L < 6 \eta$	Inertial

tation of the attached particles. The cemented particles are agglomerates. If the supersaturation is zero, no cementation occurs and all loosely agglomerated particles fall apart again. Since in practice only the combined result of disruption and cementing can be observed, an effective agglomeration rate is generally defined.

The main transport mechanisms by which particles can collide are Brownian motion, laminar or turbulent flow or relative particle setting. Depending on the particle size and the Kolmogorov length scale of the different flow regimes, different collision mechanisms can be distinguished (Table 2).

In case of orthokinetic collisions the effective agglomeration rate constant or agglomeration kernel can be described as a product of the collision rate constant and an efficiency factor:

$$\beta = \psi(\varepsilon, \sigma)\beta_{\text{coll}} \quad [69]$$

β_{coll} increases linearly with the shear rate γ , that equals $\sqrt{\varepsilon/\nu}$ in a stirred vessel, whereas the efficiency factor ψ decreases strongly with γ in this high shear region, and thus β also decreases after having reached a maximal value at a rather low shear rate value. Although β should be size-dependent, experimental agglomeration data can often be fitted with a size-independent kernel. Hounslow and co-workers recently introduced a dependence of β_{coll} on the mean particle size. The efficiency factor includes the supersaturation dependence that is needed for the cementation of the particles. The supersaturation-dependent cementation explains why, for large crystallizers with a sufficiently large circulation time between two subsequent collisions with the impeller blades, abundant agglomeration may occur, while hardly any agglomeration is noticed for small scale crystallizers.

It must also be kept in mind that agglomeration is a kinetic process that depends on collisions, and thus on the local turbulence or power input ε . Averaging the power input ε for the calculation of β might

therefore lead to a wrong estimation of the degree of agglomeration.

Industrial Crystallizers

Several types of crystallizers are commercially available. The choice of crystallizer depends on the material to be crystallized and the solvent, the method of crystallization, the product specifications, in particular the crystal size distribution, and the flexibility of the design in cases where products of various coarseness (L_{50}) must be crystallized on demand in the same equipment.

Here only three large scale evaporative and cooling crystallizers will be discussed. These examples mainly serve to illustrate that in practice and in particular for a large scale crystallizer several compartments can be distinguished, where different processes may dominate.

Forced Circulation Crystallizer

The forced circulation (FC) crystallizer is the most widely used crystallizer. It is most common in multi-stage flash evaporative crystallization of salts with a flat solubility curve. It is the least expensive vacuum crystallizer, especially for evaporation of substantial amounts of water. The crystallizer as depicted in Figure 9 comprises two separate bodies that can be designed separately for evaporation and crystallization and for heat input.

The boiling zone with often a tangential inlet of the incoming flow should be large enough for vapour

Figure 9 Forced circulation crystallizer with a tangential inlet (Swenson type). Reproduced with permission from Bennett (1993).

release, while the vessel bulk zone should maintain a sufficiently large volume to retain the growing crystals until the supersaturation is consumed. A slurry pump circulates the crystal slurry through the tubes of the heat exchanger, that can act as an internal fines dissolver, back into the boiling zone. This pump also creates most of the attrition fragments that may grow out as secondary nuclei, although usually an (axial-type) centrifugal pump is applied to minimize the attrition in order to get a sufficiently large mean crystal size. Because the forced circulation causes good mixing, the FC crystallizer is often modelled as a one compartment or MSMPR crystallizer in spite of its various zones.

The supersaturation and the turbulence may however differ locally.

Draft Tube Baffled Crystallizer

In this draft tube baffled (DTB) crystallizer with an external heat exchanger, as depicted in Figure 10, the heat duty is also separated from the crystallizer body. Fines removal has been realized by installing a skirt baffle that creates a settling or annular zone. The flow in the draft tube thus has to be upwards: this is effected by the impeller that also creates most of the attrition fragments. The fines flow can be diluted or heated to partly or totally dissolve

Figure 10 Stirred draft tube baffled (DTB) crystallizer with an external heat exchanger and fines destruction (Swenson type). Reproduced with permission from Bennett (1993).

the fines. An increase in fines flow increases the number of fines that are removed from the crystallizer, but also the cut size of the fines. The fines loop in this way serves as an actuator that can be applied for control of the mean crystal size, although the variation in mean crystal size that can be achieved is limited.

The addition of an elutriation leg at the bottom of the crystallizer or the addition of another type of classifier allows classification of the product flow, and thus also serves as an actuator to influence the CSD of the product.

Obviously the various zones of the DTB crystallizer have different functions, and different supersaturation and turbulence values can be expected, in particular for large scale crystallizers.

The DTB crystallizer can also be applied as cooling crystallizer by using the heat exchangers as a cooling system.

Fluidized Bed Crystallizer

A fluidized bed crystallizer (Figure 11) is especially designed to produce large and uniformly sized crystals. The heat duty and the crystallizer body are again separated. At the top of the bed the crystals are settled, and only the fines leave the crystallizer with the exhausted mother liquor to be circulated through the heat exchanger after mixing with the feed stream. The hot circulated flow enters the vaporizer head, where the solvent is flashed off. The supersaturated solution leaves the vaporizer through the downcomer, and enters the densely packed fluidized bed at the bottom of the crystallizer. The supersaturation is consumed on its way up, and a coarse product leaves the crystallizer at the bottom.

Secondary nucleation here results from crystal-crystal collisions. Also for this crystallizer several functions can be identified that are restricted to various zones in the crystallizer. The supersaturation and the turbulence are also not evenly distributed.

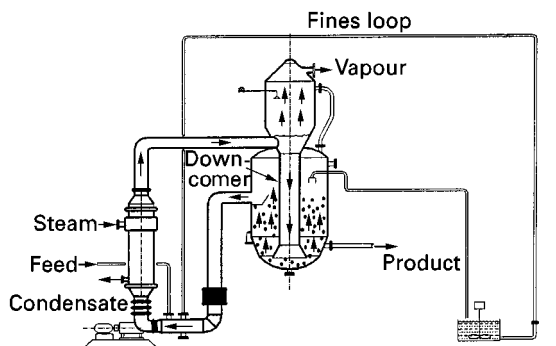

Figure 11 Fluidized bed crystallizer (Swenson type). Reproduced with permission from Bennett (1993).

Since the residence time of the crystals can be considerably increased, this type of crystallizer is commonly used to produce large crystals.

This crystallizer can also be used for cooling crystallization. No vapour chamber is then needed. Other well-known cooling crystallizers are: first, a Swenson type where the suspension is circulated through a heat exchanger; second, a direct cooling crystallizer, where a refrigerant is introduced directly into a draft tube crystallizer; and third, a cooling disc crystallizer, that can be regarded as a compact cascade of cooling crystallizers with various cooling elements that are scraped by rotating wipers.

Compartmental Modelling

In an industrial crystallizer various zones with different functions can be identified, as has been illustrated in the former section. The supersaturation (Kramer *et al.* 1999) and the turbulence (Derksen and van den Akker, 1999) in a crystallizer are therefore not necessarily evenly distributed. Their local values depend on the geometry and scale of the crystallizer,

on the flow pattern, as well as on the rates of the kinetic processes and the production rate of the specific crystallizing compound. In particular, the nonlinear kinetic processes such as nucleation and agglomeration are strongly dependent on these local values. It also has to be established whether locally the supersaturation does not exceed a maximum beyond which value rough growth occurs or too many solvent inclusions are incorporated in the crystals.

As the conventional modelling techniques use geometrically lumped descriptions (i.e. MSMPR) of the physical processes inside a crystallizer vessel (Randolph, 1998; Mersmann, 1995; Eek, 1995; O'Meadhra, 1996), they do not account for the variations in the local process conditions and have therefore seldom proven to be reliable for scale-up purposes. A reliable tool for modelling of crystallizers requires the separation of kinetics and hydrodynamics. A well-known technique for this purpose is compartmental modelling. This technique, which is frequently applied for standard reactor engineering problems, has been applied within crystallization for a number of years (Kramer, 1999).

Figure 12 (A) A DTB crystallizer and (B: a,b) two compartment structures.

Here an example will be presented to illustrate the design of a compartment model for a 360 m³ DTB crystallizer, with the main crystallizer body modelled as a one- or as a multicompartment vessel.

The subdivision of the crystallizer into multiple compartments is performed on the basis of crystallizer geometry, hydrodynamic analysis and characteristic times of the crystallization kinetics (Kramer 1999). In compartmental modelling, process conditions may differ between compartments but not within compartments, because the individual compartments are modelled as well-mixed vessels. A three-step approach is used to define the size and location of the compartments as well as the exchange flow rates between them:

1. Set up a rough compartment structure on the basis of the crystallizer geometry, e.g. an inlet compartment, a propeller compartment, a boiling zone compartment, etc.
2. Compare the characteristic time of supersaturation depletion due to crystal growth with the residence time in each compartment to check the constant supersaturation assumption. If necessary, the compartment structure may be refined.
3. Use computational fluid dynamic (CFD) results to refine further the compartment structure, specifically with respect to the exchange flow rates and the constant energy dissipation assumption in each compartment.

The importance of compartmental modelling is illustrated for a 360 m³ DTB crystallizer (Figure 12)

with ammonium sulfate and water as the model system. This crystallization system is dominated by secondary nucleation and growth. The model framework of Gahn and Mersmann (see section on secondary nucleation, above) is the most sophisticated for such systems and is hence used in this example. Figure 12 also contains two compartment structures for this DTB crystallizer. The first compartment structure (Figure 12B a) describes a MSMPR crystallizer with fines removal and fines dissolution. The second structure (Figure 12B b) was created using the three-step approach presented in the previous paragraph.

Both compartment structures will now be used to describe the behaviour of the 360 m³ DTB crystallizer operating with a residence time of 75 min, an impeller frequency of 45 rpm and a fines withdrawal rate of 157 m³ min⁻¹. Additional information regarding the equipment, operating conditions and simulation details can be found in Bermingham *et al.* (1999).

Results of simulations with both compartment structures are depicted in Figure 13. Taking the spatial distribution of the supersaturation into account clearly has a large influence on the predicted crystal size distribution. The lower median size of simulation (b) is most probably related to the higher supersaturation of the withdrawn fines flow, i.e. 1.78 as opposed to 1.38 kg m⁻³. Furthermore, it is interesting to note that a large majority of the crystal mass is produced in only half the crystallizer volume.

This example clearly illustrates the effect of varying process conditions in different zones of an industrial crystallizer on the CSD of the produced

crystals. Compartmental modelling is therefore an important or even essential tool in the design of industrial crystallizers to predict the influence of crystallizer geometry, scale, operating conditions and process actuators on the process behaviour and product quality.

Only using this approach can a reasonable prediction can be obtained for the composition of the bleed and/or product streams, and of the filterability and washability of the product, which determine the efficiency of this separation process.

Product Properties Related to the Process Conditions

In order to apply crystallization as an adequate separation process, the solid phase has to fulfil a number of requirements. The crystal size distribution as well as the shape of the crystals should meet the demands of a good filterability and washability of the product, as is needed for a good separation. The surface roughness of the crystals may also play a role, because a rough surface leads to attrition, and the attrited fragments may hamper the downstream processes.

The crystals should be formed under process conditions that minimize the uptake of impurities or mother liquor inclusions in the crystals. This can happen when the (local) supersaturation is too high. A too high local turbulence should be avoided, this causes attrition of especially the corners or edges of the crystals. Although healing of the crystals will occur particularly in the regions of the highest supersaturations, this healing process is never perfect, and always leads to the uptake of solvent inclusions. That crystals are prone to attrition beyond a certain size that also depends on the degree of turbulence can be seen from Figure 14.

Agglomeration should in general be prevented, since liquid incorporation between the primary par-

Figure 14 Liquid inclusions in $(\text{NH}_4)_2\text{SO}_4$ crystal embedded in a liquid of similar refractive index.

ticles of an agglomerate is unavoidable. Only if, as often happens in precipitation processes, the primary particles are too small for filtration, agglomeration should just be promoted. In that event the solute concentration in the mother liquor is extremely low and some incorporation of it in the solid phase hardly affects the separation process.

Final Remarks

To summarize, it can be said that the design of a good evaporative or cooling crystallization process is based on heat, mass and population balances, kinetic processes of nucleation, growth and agglomeration of the particles, as well as on the hydrodynamics that exist in the crystallizer of a given geometry and scale. However, as the prevailing process conditions are not evenly distributed in industrial crystallizers, local descriptions of the crystallization phenomena are needed to calculate the local variations in the process conditions, their effect on the process performance and to predict their dependence of the scale and geometry of the crystallizer. It has been shown that by taking all these balances and processes into account in a compartmental modelling tool, the efficiency of the separation process as well as the quality of the crystalline product and the process performance can be properly predicted.

DISTILLATION

R. Smith and M. Jobson, Department of Process Integration, UMIST, Manchester, UK

Copyright © 2000 Academic Press

Introduction

Distillation is the most commonly used method for the separation of homogeneous fluid mixtures. Separation exploits differences in boiling point, or volatility, between the components in the mixture. Repeated vaporization and condensation of the mixture allows virtually complete separation of most homogeneous fluid mixtures. The vaporization requires the input of energy. This is the principal disadvantage of distillation: its high energy usage. However, distillation has three principle advantages over alternative methods for the separation of homogeneous fluid mixtures:

1. The ability to handle a wide range of feed flow rates. Many of the alternative processes for the separation of fluid mixtures can only handle low flow rates, whereas distillation can be designed for the separation of extremely high or extremely low flow rates.

2. The ability to separate feeds with a wide range of feed concentrations. Many of the alternatives to distillation can only separate feeds that are already relatively pure.
3. The ability to produce high product purity. Many of the alternatives to distillation only carry out a partial separation and cannot produce pure products.

It is no accident that distillation is the most common method for the separation of homogeneous mixtures. It is a versatile, robust and well-understood technique. We shall start explaining distillation by a single-stage separation, before understanding how to set up a cascade of separation stages, which is distillation.

Single-Stage Separation

Consider the liquid mixture illustrated in **Figure 1**. If this liquid mixture is partially vaporized then the vapour becomes richer in the more volatile components (i.e. those with the lower boiling points) than the liquid phase. The liquid becomes richer in the less volatile components (i.e. those with the higher boiling points). If we allow the system in **Figure 1** to come to equilibrium conditions, then the distribution of the components between the vapour and liquid phases is

Figure 1 Partial vaporization of a liquid mixture creates a separation.

dictated by thermodynamic vapour–liquid equilibrium considerations. All components can appear in both phases. However, involatile components will tend to stay in the liquid phase.

Rather than partially vaporize a liquid, as shown in Figure 1, we could have started with a mixture of components in the vapour phase and partially condensed the vapour. We would still have had a separation, as the liquid which was formed would be richer in the less volatile components, while the vapour would have become depleted in the less volatile components. Again, the distribution of components between the vapour and liquid is dictated by thermodynamic vapour–liquid equilibrium considerations if we allow the system to come to equilibrium. Any noncondensable components present in the vapour will tend to stay in the vapour phase.

For each component in the mixture, thermodynamic equilibrium is given by the condition when the vapour and liquid fugacities are equal:

$$f_i^v = f_i^L \quad [1]$$

Fugacity is a thermodynamic pressure which, when substituted for pressure in thermodynamic expressions for ideal systems, allows them to be used for nonideal systems. It can be thought of as an escaping tendency. Defining the vapour phase fugacity coefficient ϕ_i^v :

$$f_i^v = y_i \phi_i^v P \quad [2]$$

Defining the liquid-phase fugacity coefficient ϕ_i^L and activity coefficient γ_i :

$$f_i^L = x_i \phi_i^L P \quad [3]$$

or:

$$f_i^L = x_i \gamma_i f_i^0 \quad [4]$$

For moderate pressures f_i^0 is usually taken to be the saturated vapour pressure P_i^{SAT} :

$$f_i^L = x_i \gamma_i P_i^{\text{SAT}} \quad [5]$$

These equations can be combined to give an expression for the constant, K :

$$K_i = \frac{y_i}{x_i} = \frac{\phi_i^L}{\phi_i^v} \quad [6]$$

This expression provides the basis for vapour–liquid equilibrium calculations based on equations of state (e.g. Peng–Robinson equation). Alternatively:

$$K_i = \frac{y_i}{x_i} = \frac{\gamma_i P_i^{\text{SAT}}}{\phi_i^v P} \quad [7]$$

This expression provides the basis for vapour–liquid equilibrium calculations based on liquid-phase activity coefficient models (e.g. Wilson equation). At moderate pressures:

$$K_i = \frac{y_i}{x_i} = \frac{\gamma_i P_i^{\text{SAT}}}{P} \quad [8]$$

When the liquid phase behaves as an ideal solution, this expression simplifies to:

$$K_i = \frac{y_i}{x_i} = \frac{P_i^{\text{SAT}}}{P} \quad [9]$$

which is Raoult's law. Correlations are available to relate component vapour pressure to temperature (e.g. the Antoine equation), activity coefficients to composition and temperature (e.g. the Wilson equation) and fugacity coefficient to mixture, pressure and temperature (e.g. from the Peng–Robinson equation of state). Regression analysis of experimental data provides the adjustable parameters used in the various models.

The ratio of equilibrium constants for two components measures their relative volatility:

$$\alpha_{ij} = \frac{K_i}{K_j} \quad [10]$$

where α_{ij} is the relative volatility between components i and j .

Figure 2 shows the vapour–liquid equilibrium behaviour for a binary mixture of benzene and toluene.

Figure 2 Vapour-liquid equilibrium for a binary mixture of benzene and toluene at a pressure of 1 atm.

Figure 2A shows the behaviour of the temperature of the saturated liquid and saturated vapour as the mole fraction of benzene is varied (the balance being toluene).

Figure 2A also shows a typical vapour-liquid equilibrium pair where the mole fraction of benzene in the liquid phase is 0.4 and that in the vapour phase is 0.62. Shown in Figure 2B is an alternative way of representing the vapour-liquid equilibrium behaviour (x - y diagram). This plots the mole fraction of benzene in the vapour versus mole fraction of benzene in the liquid. A diagonal line across this diagram would represent a situation where the concentration in the vapour and the liquid are equal. The phase equilibrium behaviour, however, shows a curve above the diagonal line. This indicates that the benzene has a higher concentration in the vapour phase than the toluene, i.e. the benzene is the more volatile component in this case. Figure 2B shows the same vapour-liquid equilibrium pair as that shown in Figure 2A with a mole fraction of benzene in the liquid phase of 0.4 versus a mole fraction in the vapour phase of 0.62.

Figure 3 shows a single equilibrium stage. Liquid is fed with composition x_0 and vapour is fed with com-

position y_2 . Contact between the vapour and the liquid streams makes the vapour richer in the more volatile components and the liquid richer in the less volatile components. Once the feed conditions and compositions, the system pressure and the relative flow rates of the vapour and liquid have been fixed, then the temperature and compositions of the exit streams are unique. Let us also, initially, make a simplifying assumption that the molar flow rates of the liquid L and molar flow rates of the vapour V are constant for the stage. This assumption is known as constant molar overflow and is true if sensible heat effects are small, molar latent heats of vaporization of the components are equal, heat of mixing is negligible and there are no heat losses or gains. Let us now carry out a mass balance around the equilibrium stage shown in Figure 3. First we assume constant molar overflow:

$$L_0 = L_1 = L \quad [11]$$

$$V_2 = V_1 = V \quad [12]$$

A component mass balance gives:

$$Lx_{0,A} + Vy_{2,A} = Lx_{1,A} + Vy_{1,A} \quad [13]$$

which can be rearranged to give:

$$y_{1,A} = -\frac{L}{V}x_{1,A} + \frac{Lx_{0,A} + Vy_{2,A}}{V} \quad [14]$$

This equation can be plotted on an x - y diagram, as shown in Figure 4. The mass balance line is a straight line which depends on the liquid and vapour flow rates and the feed compositions of liquid and vapour. In Figure 4 the liquid and vapour feeds are not in equilibrium. Following the mass balance line until it

Figure 3 Separation in a single equilibrium stage.

Figure 4 Single-stage separation for a binary mixture.

crosses the equilibrium line allows us to predict the vapour and liquid composition at the exit of the stage. We can now see quantitatively the separation carried out by the single equilibrium stage. However, the separation which is achieved on a single equilibrium stage is limited. We now need to consider how we can extend the idea to carry out further separation.

Cascade of Separation Stages

We have seen that a single equilibrium stage can only achieve a limited amount of separation. To extend the amount of separation we can make a cascade of stages, as shown in **Figure 5**. It is assumed in the cascade that streams leaving each stage are in equilibrium. Using a cascade of stages in this way allows the more volatile components to be transferred to the vapour phase, the less volatile components to be transferred to the liquid phase and a greater degree of separation to be achieved than for a single stage.

Figure 6 shows the liquid and vapour flows connecting the stages in a countercurrent cascade. As before, we assume constant molar overflow:

$$L_0 = L_m = \dots = L_N; V_1 = V_m = \dots = V_{N+1} \quad [15]$$

We can write an overall mass balance for component i across the cascade:

$$L_0 x_{0,i} + V_{N+1} y_{N+1,i} = L_N x_{N,i} + V_1 y_{1,i} \quad [16]$$

We can also write a mass balance around the envelope shown in **Figure 6** over m stages:

$$L_0 x_{0,i} + V_{m+1} y_{m+1,i} = L_m x_{m,i} + V_1 y_{1,i} \quad [17]$$

This equation can be rearranged to give:

$$y_{m+1} = \frac{L}{V} \cdot x_m + \frac{Vy_1 - Lx_0}{V} \quad [18]$$

This operating line relates the composition streams after m stages.

Figure 7 shows the cascade in terms of a more conventional representation in a distillation column. At the top of the column we need liquid to feed the cascade. This is produced by condensing and returning some of the vapour which leaves the top stage. We also need vapour to feed the cascade at the bottom of the column. This is produced by vaporizing

Figure 5 A cascade of separation stages.

Figure 6 Mass balance on a countercurrent cascade.

and returning some of the liquid leaving the bottom stage. The feed to the process is introduced at an intermediate stage; products are removed from the condenser and the reboiler (vaporizer).

The method by which the vapour and liquid are contacted with each other in distillation columns falls into two broad categories. **Figure 8** shows a plate or tray column. Liquid enters the first tray at the top of the column and flows across what is shown in **Figure 8** as a perforated plate. Liquid is prevented from weeping through the holes in the plate by the upflowing vapour. In this way the vapour and liquid are contacted. The liquid from the first tray flows over a weir and down a downcomer, to the next stage and

so on. The design of stage used in **Figure 8** involving a plate with simple holes is known as a sieve tray. Many other designs of tray are available involving, for example, valve arrangements for the holes in the trays. In practice, the column will need more trays than the number of equilibrium stages as mass transfer limitations prevent equilibrium being achieved on a tray.

The other broad class of contacting arrangement is that of packed columns. Here the column is filled with a solid material which has a high voidage. Liquid trickles across the surfaces of the packing and vapour flows upward through the voids in the packing, contacting the liquid on its way up the column. Many different designs of packing are available.

The design of a distillation column like the one shown in **Figure 8** involves a number of steps:

1. Set the product specifications.
2. Set the operating pressure.
3. Determine the number of theoretical stages required and the energy requirements.
4. Determine the actual number of trays or height of packing needed and the column diameter.
5. Design the column internals, which involves determining the specific dimensions of the trays, packing, liquid and vapour distribution systems, etc.
6. Carry out the mechanical design to determine wall thicknesses, internal fittings, etc.

Let us start by considering the simplest case of binary distillation.

Binary Distillation

Consider the mass balance on a simple distillation column. By simple column, we mean that the column has one feed, two products, one reboiler and one condenser. Such a column is shown in **Figure 9**, together with the feed and product flow rates and compositions. We can write an overall mass balance as:

Figure 7 Refluxing and reboiling.

$$F = D + B$$

[19]

Figure 8 The distillation column.

We can also write a component balance as follows:

$$Fz_i = x_{D,i}D + x_{B,i}B \quad [20]$$

Given the reflux ratio, we can express the vapour flow in terms of R :

$$V = (R + 1) D \quad [24]$$

However, to understand the design of the column more fully, we must be able to follow the mass balance throughout the column. Let us start by considering the mass balance for the part of the column above the feed – the rectifying section. **Figure 10** shows the rectifying section of a column and the flows and compositions of the liquid and vapour in the rectifying section. First we write an overall balance for the rectifying section:

$$V_{n+1} = L_n + D \quad [21]$$

We can also write a component balance:

$$V_{n+1}y_{n+1,i} = L_nx_{n,i} + Dx_{D,i} \quad [22]$$

We assume constant molar overflow (L and V are constant) and define the reflux ratio, R , to be:

$$R = L/D \quad [23]$$

Figure 9 Mass balance on a simple distillation column.

Figure 10 Mass balance on the rectifying section.

These expressions can be combined to give an equation which relates the vapour entering and liquid flows leaving stage n :

$$y_{n+1,i} = \frac{R}{R+1} x_{n,i} + \frac{1}{R+1} x_{D,i} \quad [25]$$

On an x - y diagram for component i , this is a straight line starting at the distillate composition with slope $R/(R+1)$ and which intersects the diagonal line at $x_{D,i}$.

Starting at the distillate composition x_D in Figure 10, a horizontal line across to the equilibrium line takes us to the composition of the vapour in equilibrium with the distillate, y_1 . A vertical step down takes us to the liquid composition leaving stage 1, x_1 . Another horizontal line across to the equilibrium line gives us the composition of the vapour leaving stage 2, y_2 . A vertical line to the operating line gives us the composition of the liquid leaving stage 2, x_2 , and so on. Thus, as we step between the operating line and equilibrium line in Figure 10, we follow the change in vapour and liquid composition through the rectifying section of the column.

Now consider the corresponding mass balance for the column below the feed, the stripping section. Figure 11A shows the vapour and liquid flows and compositions through the stripping section of a column. An overall mass balance for the stripping section around stage m gives:

$$L_m = V_{m+1} + B \quad [26]$$

A component balance gives:

$$L_m x_{m,i} = V_{m+1} y_{m+1,i} + B x_{B,i} \quad [27]$$

Again, assuming constant molar overflow (L and V are constant), these expressions can be combined to give an equation relating the vapour entering and the liquid leaving stage m :

$$y_{m+1,i} = \frac{L}{V} x_{m,i} - \frac{B}{V} x_{B,i} \quad [28]$$

We can plot this line in our x - y plot, as shown in Figure 11B. It is a straight line with slope L/V which intersects the diagonal line at x_B . Starting from the

Figure 11 Mass balance on the stripping section.

bottom composition, x_B , a vertical line to the equilibrium line gives the composition of the vapour leaving the reboiler, y_B . A horizontal line across to the operating line gives the composition of the liquid leaving stage N , x_N . A vertical line to the equilibrium line then gives the vapour leaving stage N , y_N , and so on.

Let us now bring together the rectifying and stripping sections at the feed stage. Consider the point of intersection of the operating lines for the rectifying and stripping sections. From eqns [22] and [27]:

$$V_{n+1}y_i = L_nx_i + Dx_{D,i} \quad [29]$$

$$V_{m+1}y_i = L_mx_i - Bx_{B,i} \quad [30]$$

where y_i and x_i are the intersection of the operating lines. Subtracting eqns [29] and [30] gives:

$$(V_{n+1} - V_{m+1})y_i = (L_n - L_m)x_i + Dx_{D,i} + Bx_{B,i} \quad [31]$$

Substituting the overall mass balance, eqn [20], gives:

$$(V_{n+1} - V_{m+1})y_i = (L_n - L_m)x_i + Fz_i \quad [32]$$

Now we need to know how the vapour and liquid flow rates change at the feed stage.

What happens here depends on the condition of the feed, whether it is sub-cooled, saturated liquid, partially vaporized, saturated vapour or superheated vapour. To define the condition of the feed, we introduce the variable q , defined as:

$$q = \frac{\text{heat required to vaporize 1 mol of feed}}{\text{molar latent heat of vaporization of feed}} \quad [33]$$

For a saturated liquid feed $q = 1$ and for a saturated vapour feed $q = 0$. The flow rate of feed entering the column as liquid is $q \cdot F$. The flow rate of feed entering the column as vapour is $(1 - q) \cdot F$. **Figure 12A** shows a schematic representation of the feed stage. An overall mass balance on the feed stage for the vapour gives:

$$V_n = V_m + (1 - q)F \quad [34]$$

An overall mass balance for the liquid on the feed stage gives:

$$L_m = L_n + qF \quad [35]$$

Combining eqns [32], [34] and [35] gives a relationship between the compositions of the feed and the

Figure 12 Mass balance for the feed stage.

vapour and liquid leaving the feed tray:

$$y_i = \frac{q}{q-1} \cdot x_i - \frac{1}{q-1} \cdot z_i \quad [36]$$

This equation is known as the q -line. On the x - y plot, it is a straight line with slope $q/(q-1)$ and intersects the diagonal line at z_i . It is plotted in Figure 12B for various values of q .

We are now in a position to bring together the mass balance for the rectifying and stripping sections. **Figure 13** shows the complete design. The construction is started by plotting the operating lines for the rectifying and stripping sections. The q -line intersects the operating lines at their intersection. The intersection of the operating lines is the correct feed stage, i.e. the feed stage necessary to minimize the overall number of theoretical stages. The construction steps off between the operating lines and the equilibrium lines. The construction can be started either from the overhead composition working down or from the bottom composition working up. The

Figure 13 Combining the rectifying and stripping sections.

stepping procedure changes from one operating line to the other at the intersection with the q -line. We should also note that a partial reboiler represents a separation stage and a partial condenser (as opposed to a total condenser) also represents a separation stage.

There are two important limits that we need to consider for distillation. The first is illustrated in **Figure 14A**. This is total reflux in which no products are taken and there is no feed. All of the overhead

vapour is refluxed and all of the bottom liquid re-boiled. Figure 14A also shows total reflux on an x - y plot. This corresponds with the smallest number of stages required for the separation. The other limiting case, shown in Figure 14B, is where the reflux ratio is chosen such that the operating lines intersect at the equilibrium line. As this stepping procedure approaches the q -line from both ends, an infinite number of steps are required to approach the q -line. This is the minimum reflux condition, and we term the condition at the feed stage to be a pinch.

This method of design for binary distillation is known as the McCabe–Thiele method. It is restricted in its application because it only applies to binary systems and involves the simplifying assumption of constant molar overflow. However, it is an important method to understand as it gives important conceptual insights into distillation, which cannot be obtained in any other way.

Multicomponent Distillation

Before a multicomponent distillation column can be designed, a decision must be made as to the two key components between which it is desired to make the separation. The light key component will be the one we wish to keep out of the bottom product. The heavy key component will be the one we wish to keep out of the top product. The recovery of the light key or the concentration of the light key in the overhead

(A)

(B)

Figure 14 (A) Total and (B) minimum reflux in binary distillation.

product must be specified, as must the recovery of the heavy key or the concentration of the heavy key in the bottom product. Intermediate boiling components will distribute between the products.

A number of short-cut methods are available for the design of multicomponent distillation columns. Each considers different aspects of the design of multicomponent columns. Each of the short-cut methods involves some simplifying assumptions and the designer must be fully aware of these assumptions when applying these methods. One simplifying assumption, which all the methods have in common, is the assumption of constant relative volatility. The relative volatility for the feed composition can be calculated, but this might not be characteristic of the overall column. By making some assumption of the product compositions, the relative volatility at the top and bottom of the column can be calculated and a mean taken:

$$(\alpha_{i,j})_{\text{mean}} = \sqrt{(\alpha_{i,j})_{\text{top}} \cdot (\alpha_i^j)_{\text{bottom}}} \quad [37]$$

Fenske Equation

The Fenske equation is used to estimate the minimum number of stages, N_{\min} . This is at total reflux and the flows of component i and a reference component, r , are related by:

$$\frac{d_i}{d_r} = \alpha_{i,r}^{N_{\min}} \cdot \frac{b_i}{b_r} \quad \text{or} \quad \frac{x_{D,i}}{x_{D,r}} = \alpha_{i,r}^{N_{\min}} \cdot \frac{x_{B,i}}{x_{B,r}} \quad [38]$$

When component i is the light key component L , and r is the heavy key component, H , we can write:

$$N_{\min} = \frac{\log \left[\frac{d_L}{d_H} \cdot \frac{b_H}{b_L} \right]}{\log \alpha_{L,H}} \quad [39]$$

$$N_{\min} = \frac{\log \left[\frac{x_{D,L}}{x_{D,H}} \cdot \frac{x_{B,H}}{x_{B,L}} \right]}{\log \alpha_{L,H}} \quad [40]$$

$$N_{\min} = \frac{\log \left[\frac{r_{D,L}}{1 - r_{D,L}} \cdot \frac{r_{B,H}}{1 - r_{B,H}} \right]}{\log \alpha_{L,H}} \quad [41]$$

Hengstebeck–Geddes Equation

The Hengstebeck–Geddes equation is used to estimate the composition of the products. The Fenske equation can be written in the form:

$$\log \left[\frac{d_i}{b_i} \right] = A + C \log \alpha_{i,r} \quad [42]$$

Figure 15 The Hengstebeck–Geddes method.

The parameters A and C are obtained by applying the relationship to the light and heavy key components. This allows the compositions of the non-key components to be estimated. This is illustrated in **Figure 15**. Having specified the distribution of the light and heavy key components, knowing the relative volatilities for the other components allows their compositions to be estimated. The method is based on total reflux conditions. It assumes that the component distributions do not depend on reflux ratio.

The Underwood Equations

The Underwood equations are used to estimate minimum reflux ratio. There are two equations. The first is given by:

$$\sum_{i=1}^n \frac{\alpha_i x_{i,F}}{\alpha_i - \theta} = 1 - q \quad [43]$$

This equation must be solved for the root θ . This root will have a value between the relative volatilities of the light and heavy key components. Having obtained the value θ , this is then substituted into the second equation to determine the minimum reflux ratio, R_{\min} :

$$R_{\min} + 1 = \sum_{i=1}^n \frac{\alpha_i x_{i,D}}{\alpha_i - \theta} \quad [44]$$

The Gilliland Correlation

The Gilliland correlation is an empirical relationship used to determine the number of stages, given the minimum reflux ratio R_{\min} and minimum number of stages N_{\min} . The original correlation was presented in

graphical form. Two parameters were used to correlate the experimental data:

$$Y = \frac{N - N_{\min}}{N + 1}, \quad X = \frac{R - R_{\min}}{R + 1} \quad [45]$$

Various attempts have been made to represent the correlation algebraically. For example:

$$Y = 0.2788 - 1.3154X + 0.4114X^{0.2910} + 0.8268 \cdot \ln X + 0.9020 \ln\left(X + \frac{1}{X}\right) \quad [46]$$

The Kirkbride Equation

The Kirkbride equation is used to estimate the most appropriate feed point for the column. It is given in the form:

$$\log \frac{N_r}{N_s} = 0.206 \log \left[\frac{z_H}{z_L} \cdot \frac{B}{D} \cdot \left(\frac{x_{B,L}}{x_{D,H}} \right)^2 \right] \quad [47]$$

Rigorous Methods

All of the above equations are approximate in some way. To develop a completely rigorous approach to distillation design, consider **Figure 16**. This shows a general stage in the distillation column. Vapour and liquid enter this stage. A liquid side-stream can be taken, as can a vapour side-stream. Feed can enter

and heat can be transferred to or from the stage. This is a general stage and allows for many design options other than simple columns with one feed and two products. By using a general representation of a stage, as shown in **Figure 16**, designs with multiple feeds, multiple products and intermediate heat exchange are possible. We can write rigorous equations to describe the material and energy balance.

1. Material balance (N_{comp} equations for each stage):

$$L_{j-1}x_{i,j-1} + V_{j+1}y_{i,j+1} + F_jz_{i,j} - (L_j + U_j)x_{i,j} - (V_j + W_j)y_{i,j} = 0 \quad [48]$$

2. Equilibrium relation for each component (N_{comp} equations for each stage):

$$y_{i,j} - K_{i,j}x_{i,j} = 0 \quad [49]$$

3. Summation equations (one for each stage):

$$\sum_{i=1}^{N_{\text{comp}}} y_{i,j} - 1.0 = 0 \quad \sum_{i=1}^{N_{\text{comp}}} x_{i,j} - 1.0 = 0 \quad [50]$$

4. Energy balance (one for each stage):

$$L_{j-1}H_{j-1}^L + V_{j+1}H_{j+1}^V + F_jH^F - (L_j + U_j)H_j^L - (V_j + W_j)H_j^V - Q_j = 0 \quad [51]$$

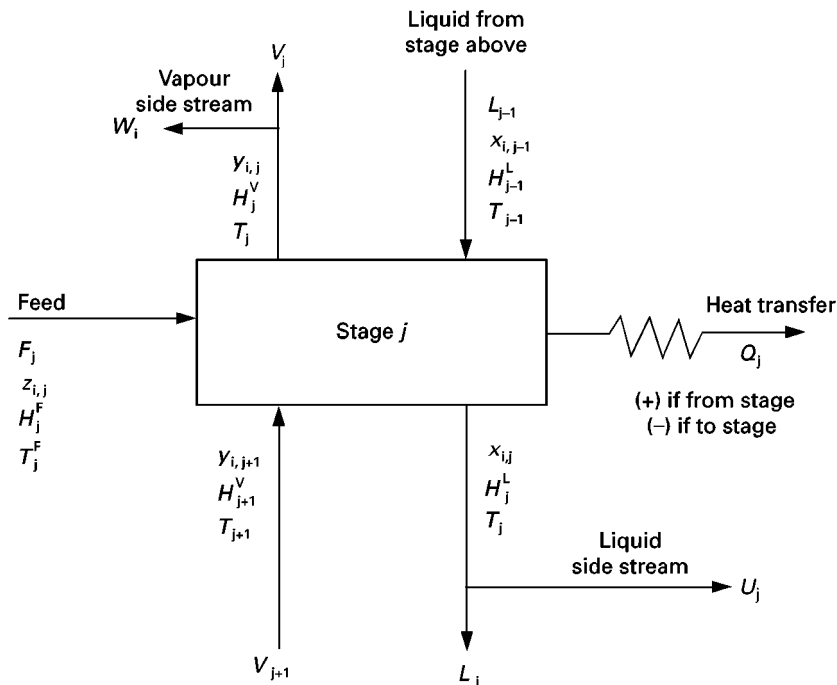

Figure 16 A general stage for rigorous methods in multicomponent distillation.

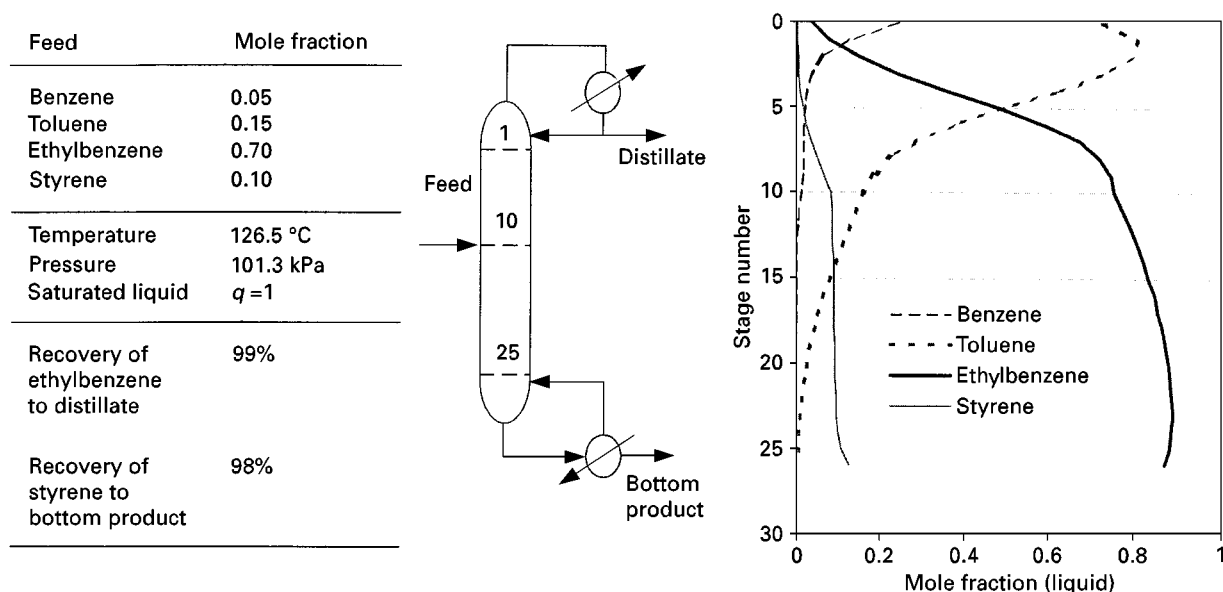

Figure 17 Simulation results for multicomponent distillation.

This set of equations must be solved iteratively and the calculations are complex. Many methods are available and in practice designers use commercial simulation packages.

Figure 17 shows a typical result for the rigorous simulation of a distillation column with a feed mixture containing benzene, toluene, ethylbenzene and styrene. Because such simulations are numerically complex and time-consuming, short-cut calculations are used to explore the various design parameters before setting up a rigorous simulation.

Choice of Operating Parameters

The feed composition and flow rate are usually fixed. Also, the product specifications are usually given in the statement of the design problem. These may be

expressed in terms of product purities or recoveries of certain components. The operating parameters to be selected by the designer include:

1. operating pressure
2. reflux ratio
3. feed condition
4. feed stage location
5. type of condenser

Pressure

Once the products have been specified, the pressure must be specified before the design can proceed. Pressure has an important effect on all aspects of the distillation column design. Figure 18 shows the trends of various properties of the distillation as

Figure 18 Effect of pressure on the distillation of a mixture of benzene, toluene, ethylbenzene and styrene.

Figure 19 Effect of temperature on utility costs.

pressure increases. As pressure increases, the relative volatility decreases, making separation more difficult. Minimum reflux ratio also increases with increasing pressure, as does the minimum number of stages. All of these trends point to operating the distillation columns at a pressure as low as possible. However, the latent heat decreases with increasing pressure; this would have the effect of decreasing the reboiler duty as pressure increases. Finally, Figure 18 also shows the trend of condenser and the reboiler temperature as pressure increases; both increase with increasing pressure.

The temperature of the condenser and reboiler, as shown in Figure 18, dictate the choice of utilities to supply heating and cooling. Figure 19 shows the trend for the variation in utility costs for heating and cooling at different temperatures. Figure 19 shows that extreme temperatures for heating and cooling require more expensive utilities. Matching the distillation condenser and reboiler against cheap utilities is usually the dominant issue when choosing the operating pressure of the distillation column.

When starting a distillation design, we usually choose to operate at atmospheric pressure unless this leads to thermal degradation of products in the reboiler because of high temperatures, or requires refrigeration in the condenser. If product degradation is a problem, then we would operate the column under vacuum conditions to decrease the temperatures of the distillation. If refrigeration is required in the condenser, then we might choose to increase the column pressure until cooling water can be used for the condenser (which means the overhead condenser temperature must be 30–40°C or higher), unless very high pressures are required for the distillation.

Choice of Reflux Ratio

Figure 20 shows the variation of the number of stages required versus the reflux ratio. Starting from minimum reflux, we require an infinite number of stages. As the reflux ratio is increased, the number of stages becomes finite and decreases towards the minimum number of stages at total reflux. Actual reflux ratios will lie somewhere between the two extremes.

Figure 21 shows a plot of annual cost versus reflux ratio. At minimum reflux ratio there is the requirement for an infinite number of stages and the annual capital cost is correspondingly infinite. However, as the reflux ratio is increased the capital cost diminishes. On the other hand, as reflux ratio is increased from the minimum, the utility costs increase steadily. Combining the annual capital costs with the annual utility costs gives a total annualized cost which shows a minimum at the optimum reflux ratio. This optimum is usually fairly flat for a significant range of reflux ratios and an initial setting of 1.1 times the minimum reflux ratio is often assumed.

Choice of Feed Condition

The feed condition affects vapour and liquid flow rates in the column, and in turn:

1. reflux ratio, heating and cooling duties
2. column diameter
3. most appropriate location of the feed stage

Figure 20 Range of reflux ratios.

Figure 21 Capital–energy trade-offs determine the optimum reflux ratio.

The feed temperature usually lies between the extreme temperatures of the column (condenser and reboiler temperatures).

Cooling the feed:

1. decreases the number of stages in the rectifying section but increases the number of stages in the stripping section
2. requires more heat in the reboiler but decreases the cooling duty of the condenser

Heating the feed:

1. increases the number of stages in the rectifying section but decreases the number of stages in the stripping section
2. decreases the heat requirement of the reboiler but increases the cooling duty of the condenser

Heating or cooling the feed can reduce energy costs. If heat is added to the feed and saves heating in the reboiler, the heating of the feed can be carried out at a lower temperature than would be required in the reboiler. Cooling the feed can be carried out at a lower temperature than cooling in the condenser. In both cases heating or cooling the feed is done at more moderate temperatures and, in principle, with a cheaper utility.

Choice of Feed Stage Location

When choosing the feed stage location, our objective is to find a stage in the column for which the composition matches as closely as possible that of the feed. For binary distillation it is, in theory, possible to find an exact match between the composition on a stage and the composition of the feed. In practice, because there is a finite change from stage to stage, even for

a binary system, an exact match may not be possible. In multicomponent systems it is highly unlikely that the composition of all of the components can be matched. Mismatches between the composition on the feed stage and that of the feed create inefficiencies in the distillation. These inefficiencies lead to an increase in the number of stages required for the same separation, or more reflux, which means increased energy requirements, or a combination of both.

Distillation Equipment

Let us now turn our attention to the equipment used for distillation operations. As pointed out previously, there are two broad classes of internals used for distillation: trays and packing.

Trays

Figure 22A shows a conventional tray arrangement. Liquid flows down a downcomer across a tray in which the upflowing vapour contacts the liquid flowing across the tray. The liquid flows down the next downcomer to the following tray, and so on. The perforated plate used in Figure 22A, known as a sieve tray, is the most common arrangement used. It is cheap, simple, and well understood in terms of its performance. There are many other designs of tray which are used. Many use simple valve arrangements in the holes to improve the performance and the flexibility of operation to be able to cope with a wider variety of liquid and vapour flow rates in the column. One particular disadvantage of the conventional tray in Figure 22A is that the downcomer arrangement makes a significant proportion of the area within the column shell not available for contacting liquid and vapour. In an attempt to overcome this, high capacity trays, with increased active area, have been developed. Figure 22B illustrates the concept. Again, many different designs are available for high capacity trays.

When designing a column to use trays, we need to know the tray efficiency to convert from

Figure 22 Distillation trays. (A) Conventional tray; (B) high capacity tray.

theoretical stages to real trays. The difference between the performance of an ideal stage and a real tray results from the fact that equilibrium is not achieved on a real tray because of mass transfer limitations. We therefore define an efficiency to convert from the theoretical stages to real trays. Three different efficiencies can be defined:

1. Overall tray efficiency, E_o :

$$E_o = \frac{\text{number of theoretical stages}}{\text{number of real stages}} \quad [52]$$

E_o depends on the design of the tray and the mixture being distilled and typically varies between 60% and 90% for distillation.

2. Murphree tray efficiency, E_M . This characterizes the performance of individual trays rather than having an overall measure as defined by E_o . This is because efficiencies can vary throughout the column. The Murphree tray efficiency for stage j is defined as:

$$E_M = \frac{y_j - y_{j+1}}{y_j^* - y_{j+1}} \quad [53]$$

The Murphree tray efficiency measures the change in concentration of the vapour phase for an actual tray relative to that for an ideal stage.

3. Point efficiency, E_{MP} . This measures the efficiency not only of an individual tray but at a local point on a tray. It is defined in the same way as the Murphree tray efficiency, but at a point on the tray. It is defined as:

$$E_{MP} = \frac{y_{j,\text{local}} - y_{j+1,\text{local}}}{y_{j,\text{local}}^* - y_{j+1,\text{local}}} \quad [54]$$

E_{MP} varies across the tray and must be integrated across the tray to obtain E_M . The result will depend on the mixing pattern on the tray. For example, if the tray is perfectly mixed then $E_M = E_{MP}$.

Correlations are available to predict E_o , E_M and E_{MP} .

Trays have a range within which they can operate satisfactorily in terms of the hydraulic design. For example, Figure 23 shows the range of operation of a sieve tray. Using a sieve tray, internal flows in the distillation column are limited by:

1. flooding, in which liquid cannot flow down the column
2. entrainment, in which liquid drops are carried up the column by the vapour flow

Figure 23 Sieve tray performance.

3. downcomer backup, in which liquid backs up in the downcomers
4. weeping, in which vapour flow is too low to maintain liquid on the tray
5. coning, in which poor vapour-liquid contact occurs due to the vapour forming jets

Packing

Figure 24A shows a traditional design of packing, which is random or dumped packing. The random or dumped packing is pieces of ceramic, metal or plastic which, when dumped in the column, produce a body with a high voidage. The liquid trickles down over the surfaces of the packing and the vapour is in contact with the liquid as it flows up through the voids in the packing.

Figure 24B shows structured packing. This is manufactured by sheets of metal being preformed

Figure 24 Distillation packing. (A) Random or dumped packing; (B) structured packing.

Figure 25 Flood point correlation for packing.

with corrugations and holes and then joined together to produce a preformed packing with a high voidage. This is manufactured in slabs and built up in layers within the column.

Many types of both random and structured packing are available. We need to be able to calculate the height of packing required by relating to the theoretical stages to the height of packing. For this we need the height equivalent of a theoretical plate, HETP. Thus, the packing height is simply the product of the number of theoretical stages and the HETP. Correlations are available for HETP.

As with the hydraulic design of trays, packing has a limited range over which the hydraulic design is acceptable. At very low vapour velocities through the packing, liquid flows are not influenced by the vapour flow. As the vapour velocity increases, the vapour starts to hinder the downward flow of liquid. This is the loading point. A limit is reached at a high vapour velocity, characterized by heavy entrainment of liquid and a sharp rise in the pressure drop across the packing. This is the flood point. Correlations are used to determine the flood point and a typical correlation is shown in **Figure 25**. We usually design the packing for a vapour velocity to be some proportion of the flooding velocity (e.g. 80%).

Complex Distillation Arrangements

All of the distillation arrangements which we have considered so far have involved one feed, produced two products, have a reboiler and condenser, and operation has been assumed to be continuous. Distillation designs have been adapted to suit different purposes, as discussed below.

Batch Distillation

In batch distillation, the feed is charged as a batch to the base of the distillation column. Once the feed has been charged, it is subjected to continuous vaporization. This vapour would then flow upwards through trays or packing to the condenser and reflux would be returned as with continuous distillation. However, unlike continuous distillation, the overhead product will change with time. The first material to be distilled will be the more volatile components. As the vaporization proceeds and product is withdrawn overhead, the product will become gradually richer in the less volatile components. Thus, batch distillation allows different fractions to be taken from the same feed. The batch distillation strategy depends on both the feed mixture and the products required from the distillation. By careful control of the reflux, it is possible to hold the composition of the distillate constant for a time until the required reflux ratio becomes intolerably large, as illustrated in **Figure 26**.

Azeotropic Distillation

Figure 27 shows an x - y diagram in which the equilibrium curve crosses the diagonal line. At the point where the equilibrium curve crosses the diagonal, the vapour and liquid have the same composition; this is an azeotrope. A mixture in which the vapour and liquid have the same composition cannot be separated by conventional distillation. There are two means by which a mixture such as that shown in **Figure 27** can be separated. The first uses two columns operating at different pressures and takes advantage of the fact that the composition of the azeotrope might change significantly with a change in

Figure 26 Reflux ratio can be varied in batch distillation to maintain overhead product purity.

pressure. The second method is to add a mass separation agent (known as an entrainer or a solvent). The mass separating agent must change the relative volatility of the original mixture in a way which allows the separation to be achieved.

Steam Stripping

Sometimes live steam is added at the base of the distillation column. When steam is used in this way, for example for the separation of hydrocarbon mix-

tures, the steam acts as an inert carrier, the presence of which decreases the partial pressure of the components in the vapour phase. This is like operating the distillation column at a lower pressure as far as the separation is concerned. However, the use of stripping steam is not quite the same as reducing the operating pressure.

Intermediate Reboiling and Condensing

Rather than use a single reboiler at the bottom of the column and a single condenser at the top of the column, it is possible to add or reject heat at intermediate points within the column. Below the feed but above the base of the column, liquid can be withdrawn from one of the stages into an intermediate reboiler to be vaporized and the vapour returned to the column. This inter-reboiling substitutes part of the reboiling at the base of the column. The advantage of inter-reboiling is that the heat can be supplied at a lower temperature in the inter-reboiler, compared with the temperature required for the reboiler at the base of the column.

Similarly, vapour can be withdrawn from the column above the feed but below the top of the column, condensed and the liquid returned to the column. Cooling in the intercondenser substitutes cooling in the overhead condenser. Because the cooling in the intercondenser is carried out at a higher temperature than the overhead condenser, this can have advantages in terms of the utility costs. In practice, it is difficult to extract part of the vapour flowing up

Figure 27 Azeotropic behaviour.

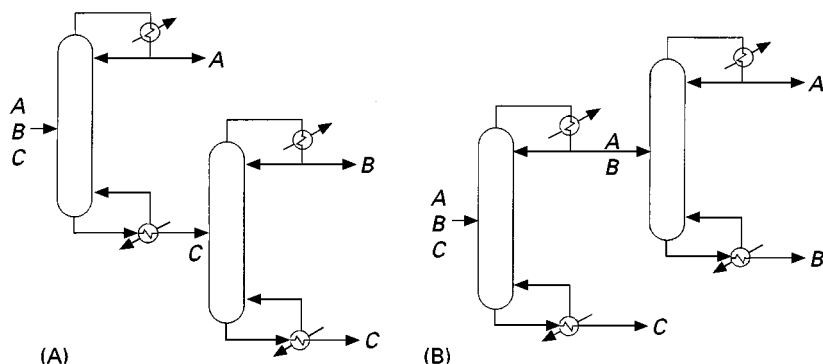

Figure 28 Sequencing simple distillation columns. (A) Direct sequence; (B) indirect sequence.

the column into an intercondenser. Because of this, it is more usual to take a liquid side-stream from the column, sub-cool the liquid and return the sub-cooled liquid to the column. The sub-cooled liquid provides condensation directly. Such arrangements are known as pump-arounds or pump-backs.

Multiple Feeds

Sometimes it is necessary to separate two or more streams with the same components but with different compositions. If this is the case, it is wrong to mix the streams with different compositions to produce a single feed for the distillation column. This is because we would mix streams only to separate them later and this is thermodynamically inefficient. If we have several streams with the same components but significantly different compositions, then it is better to feed them to the distillation column at different points, trying as much as possible to match the composition of each feed with that of one of the stages in the column.

Multiple Products

It is sometimes possible to withdraw more than two products from the same column. Part of the liquid flowing down the column or part of the vapour flow-

ing up the column can sometimes be taken as a side-stream to form a third product. Such side-stream column designs are only possible under special circumstances.

Column Sequences

If a feed mixture needs to be separated into more than two products, then more than one distillation column will usually be required. Figure 28 illustrates the options for the separation of a mixture of three products. In the first arrangement, the lightest component is taken overhead first and the two heavier products are separated in the second column. In the second arrangement, the heaviest product is separated first and then the two lightest products are separated in the second column. For a three-product separation, there are two possible sequences, as shown in Figure 28. As the number of products in the mixture increases, the number of possible distillation sequences increases significantly. For example, if we have six products, then there are 42 possible sequences of columns.

Thermal Coupling

Figure 28 showed different arrangements of simple distillation columns for the separation of a three-product mixture. Each column had one feed,

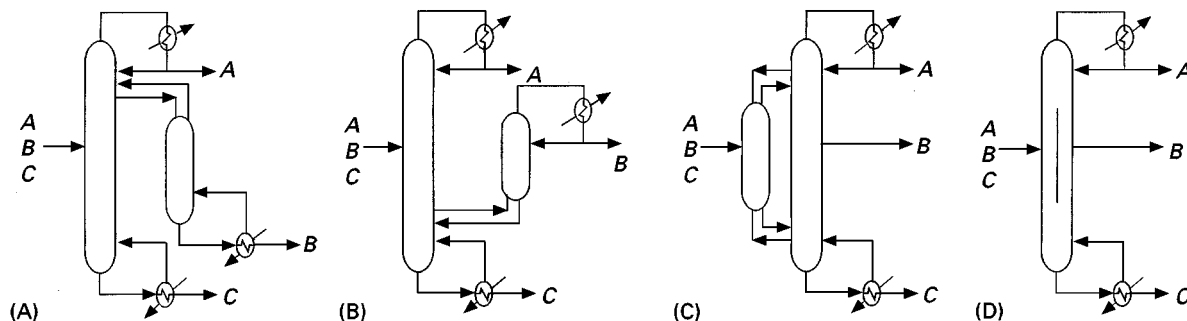

Figure 29 Thermally coupled columns. (A) Side-stripper, (B) side-rectifier; (C) fully thermally coupled (Petlyuk) column; (D) dividing wall column.

Table 1 Cases not suited to separation by distillation

<i>Case</i>	<i>Problem</i>	<i>Possible solutions</i>
Separate materials of low molecular mass	Low condensation temperature	Absorption, adsorption, membranes
Separate heat-sensitive materials of high molecular mass	Thermal degradation of products	Vacuum distillation
Separate components present in low concentrations	High flow rates in columns	Absorption, adsorption
Separate classes of components (e.g. aromatics from aliphatics)	Boiling temperatures/volatilities of components in a class are not adjacent	Liquid-liquid extraction
Separate components with similar relative volatilities	Difficult separation: high operating and capital costs	Add mass separating agent and employ extractive or heterogeneous distillation or liquid-liquid extraction, crystallization
Separate components which form an azeotrope	Azeotrope limits product composition	Add mass separating agent and employ extractive or heterogeneous distillation or liquid-liquid extraction, crystallization
Separate volatile and involatile components	Distillation requires that all components are mobile for countercurrent flow	Evaporation, drying, nanofiltration
Separate condensible and noncondensable components	Only partial condenser can be used overhead	Use single-stage separation (flash)

two products and had a reboiler and a condenser. Sometimes, it is desirable to exchange heat between columns directly using thermal coupling connections. Figure 29 shows some thermally coupled distillation designs for the separation of a three product mixture. Figure 29A shows a side-stripper and Figure 29B a side-rectifier. Figure 29C shows a fully thermally coupled arrangement, sometimes known as a Petlyuk column. Figure 29D shows what is known as a dividing wall column. This is the same arrangement as the Petlyuk column but the arrangement is built in a single shell with a dividing wall down the middle of the column. The arrangements in Figure 29C and 29D are both equivalent thermodynamically, if there is no heat transfer across the dividing wall in Figure 29D.

Summary

Distillation is a versatile, robust and well-understood technique and is the most commonly used method for the separation of homogeneous fluid mixtures. There are cases for the separation of homogeneous fluid mixtures for which distillation is not well suited. Table 1 presents a summary of these cases, along with possible solutions. It should be noted, however, that even though distillation is not well suited to the separation duties in Table 1, distillation is still used in some form for many of these problematic cases.

An Outline of the Historical Background to Electrophoretic Separations

The movement of charged particles under the influence of an electric field was observed as long ago as 1807 by Ferdinand Frederic Reuss. In 1909, the term, electrophoresis, was introduced by Michaelis as a description of this phenomenon and is derived from the Greek word *elektron* meaning amber (i.e. electric) and *phore* meaning bearer. Yet it was not until the 1930s that electrophoresis, as we know it today, developed from the work of Tiselius, who, in 1948, was awarded the Nobel Prize for this development. Table 1 charts the development of the technique over the last century. By the 1950s electrophoresis was a common laboratory technique equivalent in usefulness to planar chromatography techniques such as paper and thin layer. However, with the advent of high-performance liquid chromatography (HPLC) in the 1970s, analytical electrophoresis became something of a 'Cinderella' technique. Only in biochemical and clinical laboratories did electrophoresis continue in use as a qualitative separation technique for macromolecules, such as proteins and DNA.

It has been claimed that currently at least half of all separations are performed by electrophoresis since separations of blood proteins and DNA digests are routinely performed by the technique. The technique is now so routine in biomedicine and related disciplines that it is rarely referred to in the abstracts and titles of papers where it is a core technology, for example DNA sequencing. Even so, it is mentioned by name in almost as many papers as is chromatography (Table 2). However, with the development of

capillary electrophoresis after 1981 electrophoresis has returned as a substantial topic of interest to mainstream analytical chemistry.

Fundamentals of Electrophoresis

Unlike chromatography, there is no formal International Union of Pure and Applied Chemistry (IUPAC) definition of electrophoresis, although one is being developed at the time of writing. However, through teaching the subject over the past 10 years, I have developed the following definition:

'Electrophoresis is a mainly analytical method in which separations are based on the differing mobilities (i.e. speed plus direction of movement) of two or more charged analytes (ionic compounds) or particles held in a conducting medium under the influence of an applied direct current electric field' (Figure 1).

Electrophoresis therefore contrasts to chromatography which is defined as a method used primarily for the separation of two or more components of a mixture, in which the components are distributed between two phases, one of which is stationary while the other moves. Another difference is that in chromatography the modelling of the separation from first principles is complex, difficult and imprecise whereas a relatively simple theoretical background to electrophoresis has been developed and is reproduced below. For a more complete discussion of electrophoretic theory see Mosher *et al.* (1992).

In electrophoresis the movement is towards the electrode of opposite charge to that of the particle or ion being separated. Cations are positively charged ions and move towards the negative electrode (the cathode). Anions are negatively charged ions and move to the positive electrode (the anode). It is important to note that neutral species do not move under the influence of the electric field, although they

may diffuse from the load position or be carried by electroosmotic flow.

The rate of migration (velocity) of any charged particle in an electric field can, at its simplest, be

considered to be the vector sum of a driving force (the electrical force) and any resisting or aiding forces.

Any ion, compound or body carrying an overall charge at a given pH value will move in solution

Table 2 Separation techniques in biomedicine and related areas

Separation mode	Type	Total number of papers
Electrophoresis	All modes	150 000
	Simple planar	13 800
	Sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE)	78 000
	Immuno	19 700
	Isoelectric focusing	14 400

Chromatography	All modes	250 000
	Planar	52 000
	Column	98 000
	High-performance liquid chromatography	62 500
	Gas chromatography	32 000

Papers in Medline and on the author's database from 1976 to 1999.

Figure 1 The basic principle of all electrophoretic separations is that charged ions attempt to move in an electric field towards the electrode of opposite polarity. Neutral compounds do not move.

under appropriate conditions. In simple solutions, ions will move freely toward the electrode of opposite charge and the product of the charge on the ion and the applied electric field (E) gives the electric force experienced by the ion. However, since even a simple ion can be considered as a particle this movement is opposed by a frictional drag given by Stokes' law.

The driving force is represented by the potential gradient along which the charged particle moves and is given by the electric field strength (E):

$$E = \frac{\text{applied voltage}}{\text{distance between electrodes}} = \frac{V}{D} \quad [1]$$

The applied field (F_{ef}):

$$F_{\text{ef}} = qE \quad [2]$$

where q is the total charge on the ion.

The friction (F_{fr}) drag is given by:

$$F_{\text{fr}} = 6\pi r v \eta \quad [3]$$

where η is the viscosity of the media, r is the 'radius' of the molecule and v is the velocity.

On applying a voltage there is a rapid acceleration of all the molecules and equilibrium is achieved in a few microseconds. A vector diagram at equilibrium for movement in an electric field is shown in **Figure 2**, and under such circumstances the following equilibrium conditions apply:

- at equilibrium:

$$F_{\text{ef}} = F_{\text{fr}} \quad [4]$$

- therefore:

$$qE = 6\pi r v \eta \quad [5]$$

Figure 2 A vector diagram for movement in an electric field at equilibrium.

- so the velocity is given by:

$$v = \frac{qE}{6\pi r \eta} \quad [6]$$

Mobility (μ) is defined as the average velocity with which an ion moves under unit applied electric field under defined conditions:

$$\mu = \frac{\text{average migration velocity}}{\text{electric field strength}} = \frac{v}{E} \quad [7]$$

Substituting for v from eqn [3]:

$$\mu = \frac{q}{6\pi r \eta} \quad [8]$$

Mobility can therefore be interpreted as proportional to a charge-to-size ratio for a molecule in a given buffer at a set pH. Absolute mobility is the apparent or measured mobility corrected by any other effects adding to or subtracting from the absolute mobility (an example is electroosmotic drift). Sometimes, the term relative mobility is used when the apparent mobility of one compound is calculated in relation to another compound.

The units of μ are cm s^{-1} divided by V cm^{-1} and are therefore $\text{cm}^2 \text{V}^{-1} \text{s}^{-1}$. The magnitude of μ for typical small ions is of the order of $10^{-6} \text{cm}^2 \text{V}^{-1} \text{s}^{-1}$, e.g. for the sodium ion, $\mu = 5 \times 10^{-6} \text{cm}^2 \text{V}^{-1} \text{s}^{-1}$ or for the protein albumin, $\mu = -1.5 \times 10^{-4} \text{cm}^2 \text{V}^{-1} \text{s}^{-1}$. Note the difference in the sign of the mobility and hence the direction of movement.

A small, highly charged species, for example, an ion, will have a high mobility and a large ionizable compound, such as a protein, will have a low mobility. It is clear that electrophoresis can readily separate large and small ionic species. Then, for two or more closely related ionic species, if the basic descriptors used in eqn [6] are known, it should be a simple matter to calculate the separation conditions and the degree of resolution that can be achieved. The charge on an ionizable molecule, such as an amino acid, is determined by the pH of the electrophoretic medium. The viscosity of the medium at a given temperature will also be known precisely. The difficulty from a theoretical predictive standpoint is to determine the radius of a molecule. Many attempts have been made to calculate this value from first principles and these are discussed later. It is also clear that the distance moved is proportional to the applied voltage and the time period over which the voltage is applied.

The above analysis of the movement is a further simplification in that the resisting forces are not just

due to simple frictional drag but can also include effects such as:

- size and shape of the molecule;
- electrolyte concentration;
- solubility;
- adsorption to surfaces;
- complexation with species in the electrolyte solution.

The two basic electrical equations that govern electrophoresis are first Ohm's law which states that $V = iR$, where i is the current and R is the resistance. Secondly, power, that is the product of current and voltage or, alternatively, the heat generated is given by $i^2R = W$ where W is power measured in watts. This heating effect is termed Joule heating. The quantity of heat generated is, of course, time dependent. The development of heat and then temperature gradients in electrophoresis leads to:

- convection currents;
- diffusional/thermal broadening;
- evaporation;
- viscosity changes;
- pH variations;
- thermal degradation of analytes especially proteins and matrices.

These changes all result in band broadening and the lower resolution of separated analytes. Heat can also lead to gels drying, buffers boiling and in extreme situations even fires.

The effect of heating processes on electrophoretic separations is complex and often variable. Traditionally, workers have countered these effects by using buffers that generate low currents, for example dilute buffer solutions, low conductivity buffers, by operating at low voltages (100–500 V), operating in constant current or constant power modes and, of course, using external cooling systems, such as circulating cold water around the instrument.

Electroosmosis

The second important effect in electrophoresis is electroosmotic flow (EOF) or electroosmosis. If ionized groups cannot migrate in an electrical field (e.g. when part of a static support medium) then the liquid adjacent must move in order to maintain thermodynamic equilibrium. This EOF is seen as a bulk movement of liquid over a solid surface. In the case of silica or the carboxyl residues on a sheet of paper, the water will move in the direction of the cathode with a characteristic mobility (μ_{eof}) depending on pH. The

μ_{eof} is related to the zeta-potential of the solid surface and the dielectric constant of the electrolyte. As with mobility of an ion, μ_{eof} also varies with the viscosity of the electrolyte. The magnitude of the EOF is pH dependent. EOF leads to diffusional broadening of separated bands in slab electrophoresis but is used to good effect in capillary electrophoresis (see later section).

The Modes of Electrophoresis

There are four fundamental modes of electrophoresis, at least, in the traditional planar formats, namely moving boundary electrophoresis, zone electrophoresis, isoelectric focusing and isotachopheresis.

Moving Boundary Electrophoresis

This was the method that was studied by Tiselius in his detailed development of electrophoresis.

In this system the sample plus buffer are placed in the appropriate sample reservoir (electrolyte chamber). Tiselius used a U-tube containing the sample mixed with the buffer and the electrodes were dipped into each end. A single buffer solution therefore connects the two electrodes by way of the separation matrix. When the potential is applied, the analytes in the sample separate according to their differing mobilities. In the situation shown in **Figure 3** the cation of highest mobility moves ahead of the rest such that its front is resolved from the others. However, only the fastest analyte and, possibly, the slowest are truly separated and then only partly. The resolution of the components from others then diminishes. Tiselius observed the separated analytes via changes in their refractive index using Schlieren optics. Today such a separation mode is of little practical use except possibly in a preparative mode.

Figure 3 (See Colour Plate 6) The principle of moving boundary electrophoresis.

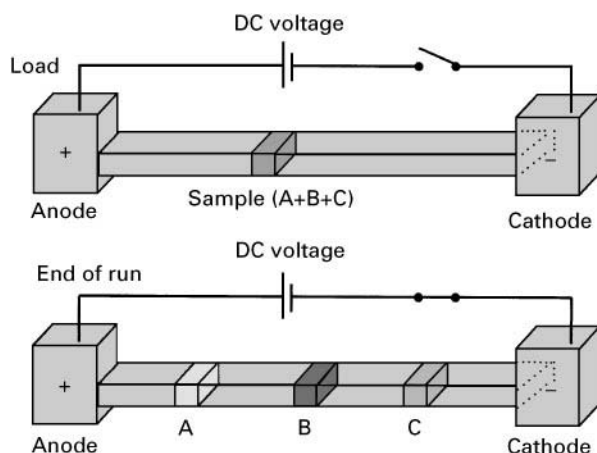

Figure 4 (See Colour Plate 7) The principle of zone electrophoresis.

Zone Electrophoresis

This is probably the most common form of electrophoresis in both slab and capillary formats (see **Figure 4**). The sample is loaded as a discrete plug or zone into a buffered electrolyte filled media such as a gel. The load point is somewhere between the electrodes in the middle if the charge on the analytes is not known or nearer to one than the other if the ionic nature of the analytes is known. The two electrode chambers and the matrix contain the same buffer. On application of the voltage, which in traditional systems is 100–500 V DC, the components of the sample migrate at different speeds and possibly in differing directions due to their differing

mobilities and their respective charges. So, after an appropriate time period, they will have separated into (hopefully) distinct zones. Turning off the voltage terminates the separation. The degree of separation will depend on the voltage applied, the distance over which the sample separates and the time as well as the nature of the analytes and the buffer. The resultant zones will most often be of a distribution that is broader than the original loading zone due to the thermal mixing and so on that will have occurred during the separation process. With few exceptions some means of revealing the zones such as staining will be necessary.

The major factor controlling the mobility of the analytes in zone electrophoresis is the pH of the buffering electrolyte. For most ionic species the buffer controls the degree of ionization via the relationship expressed in the following equation (Henderson–Hasselbach equation):

$$\text{pH} = \text{pK}_a + \log(1/\alpha - 1) \text{ for anions,} \\ -\log(1/\alpha - 1) \text{ for cations} \quad [9]$$

For analytes such as peptides or proteins which contain a number of independently ionizable groups, the overall charge on the molecule is given by summing the contribution from each group at the pH in question:

$$\mu_{\text{eff}} = \sum \alpha_i m_i \quad [10]$$

where $m_i = \mu_i$ of each completely ionized form and α_i is the degree of ionization of each ionized form. An example of the change in charge for a number of different peptides is shown in **Figure 5**.

Figure 5 An example of the change in charge for a number of different peptides. ■, AT1; □, AT2; ◆, AT3; ◇, AT4; ▲, AT5, △, AT6; ●, AT7; ○, AT9; ×, AT10; ×, AT11; |, AT14.

Since the mobility of an ion is a charge-to-size ratio (eqn [8]), one way to modify this for macromolecules is to change the size and shape of the molecules. For proteins this may be brought about by configuration changes due to changes in the pH, and in the case of DNA by incorporating an intercalating agent such as ethidium bromide. It is less simple to change the size and shape of small molecules, but one possible technique is complexation. For example, sugars will complex with borate ions in borate buffers and metal ions can complex with both peptides and nucleotides.

Equation [8] also indicates that mobility is dependent on the frictional drag exerted by the background electrolyte; in other words its viscosity. Adding agents such as polyethylene glycol (PEG) or cellulose derivatives to the buffer can increase viscosity and hence change the separation achieved.

Isoelectric Focusing

Isoelectric focusing (IEF) is steady-state electrophoresis in a pH gradient. Ionic compounds migrate to the point in the gradient where they have zero overall charge and therefore zero net mobility. For proteins this means that they migrate to their isoelectric point (pI value). The pH gradients used can be linear or nonlinear and cover either wide pH ranges, for example, 2–10 or narrow ranges (< 2 pH units). The pH gradient is formed by the application of a voltage to a mixture of amphoteric compounds (ampholytes) with closely spaced pIs encompassing a chosen pH range. A mix of at least 200 individual ampholyte species is required to establish a pH gradient of 4–10. Typically, the protein mixture is mixed with ampholytes and the resultant mixture is placed between the electrodes (Figure 6). The synthesis of such carrier ampholytes by attaching carboxylic acid moieties to polyvalent amines was perfected by Vesterberg in the

Karolinska Institute in 1964. Even the first application showed the remarkable resolving power of IEF when two myoglobin molecules differing in pI by only 0.05 pH units were resolved.

The resolving power of IEF is very high and is described by the following equation:

$$\Delta pI = \left(\frac{D(dpH/dx)}{-E(d\mu/dpH)} \right) \quad [11]$$

where D is the diffusion coefficient, E is the electric field strength and μ is the mobility of the proteins. Good resolution between analytes is therefore favoured first by low diffusion coefficients (i.e. ideal for proteins) and a steep mobility profile through their pI, and secondly by high field strengths and a shallow pH gradient.

Once a protein has reached its pI position in the pH gradient, effects such as diffusion and EOF will cause some drift from the focused zone. This drift is countered by the fact that the protein will develop a small amount of ionization and migrate back to its pI position in the pH gradient and so become re-focused. Focusing takes time, depending on the voltage used and the nature of the analytes: electrophoresis may need several hours before a steady-state is reached. Proteins are therefore resolved into narrow concentrated bands. In fact this concentrating effect is such that solubility problems can occur.

IEF was commercialized by LKB and the carrier ampholytes marketed under the tradename of Ampholine. The use of polyacrylamide gels was introduced to simplify the IEF methodologies. Although commercialized, the early ampholyte systems were in simple solution but separations tended to be irreproducible due to drifting towards the electrodes due to EOF effects. Modern IEF uses immobilized ampholytes that were developed by Righetti and co-workers in 1982. In such systems the ampholytes are immobilized to a gel matrix usually contained in a thin cylinder and so giving stable pH gradients in an easy to use format. The resolving power of these new gels with immobilized pH gradients (IPG) was much improved and permitted resolution to 0.001 pH units. More recent systems, such as the Pharmacia IPGphor, use ampholytes immobilized on flexible plastic strips. Once focused, the strips can be easily transferred to a second dimension or even used as the target in mass spectrometry.

Isotachopheresis

Isotachopheresis (ITP) is a form of steady-state electrophoresis in which a voltage gradient generated by

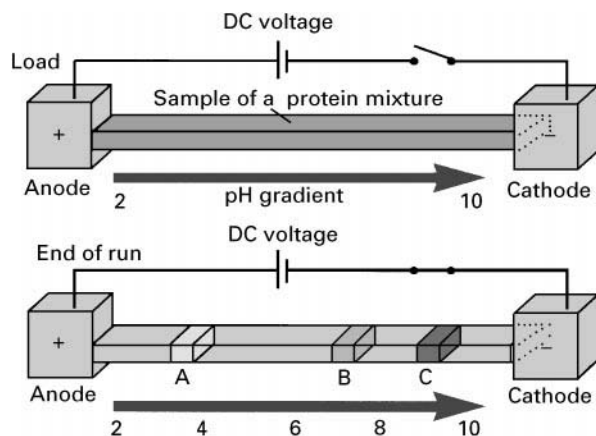

Figure 6 (See Colour Plate 8) The principle of isoelectric focusing.

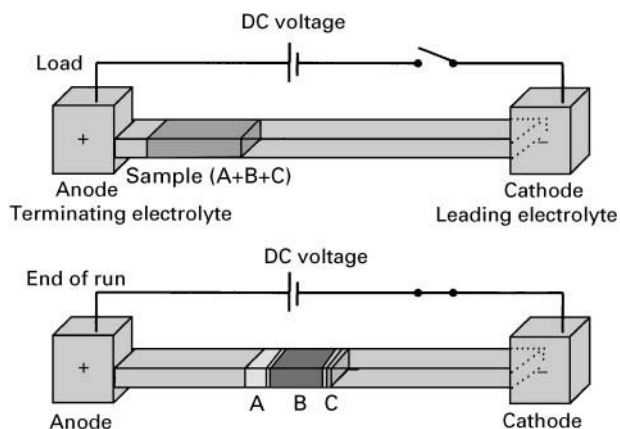

Figure 7 (See Colour Plate 9) The principle of isotachopheresis.

using buffers of differing mobility at constant current is used. It is therefore a discontinuous system. Electrophoresis proceeds until all ionic analytes are migrating with the same (*iso*) speed (*tacho*) (Figure 7). The theory is dependent on the Kohlraush regulatory function (1897), which defines the conditions at the boundary between two different ions A and L such that

$$[A] = [L] \times \text{a constant}$$

For ITP to occur, an unbuffered sample should be placed between a leading electrolyte whose $\mu_{\text{buffer ion}} \gg \mu_{\text{sample}}$ and a terminating electrolyte with a $\mu_{\text{buffer ion}} \ll \mu_{\text{sample}}$. Leading electrolytes are usually small ions such as chloride and the terminating electrolytes are larger buffer ions such as histidine.

Applying the voltage causes the analytes to separate into zones according to their mobilities, but they must remain adjacent in order for the current to be carried. From Ohm's law all zones including the terminating and leading electrolytes must carry the same current so R and V must increase. When a steady-state is obtained all bands have the same ionic concentration because they must have the same R so they will be of differing lengths. Zones must therefore increase in concentration to match the concentration of the leading electrolyte. The resultant output is usually observed as a series of steps in a conductivity trace in which the length of each band is proportional to the amount of analyte. Since analysts are usually happier looking at peaks, these traces are often differentiated in order to generate a profile with peaks so that the distance between the peaks can be measured. The development time is proportional to the amount of sample injected and to the differences in μ of the sample components.

LKB devoted considerable sums of money to develop a commercial ITP system (the Tachophore) in the late 1970s but this was a commercial failure. Commercial systems are still available from Japan (Shimadzu) and the Czech Republic (Villa Labco). Although ITP is little used today as an analytical tool, it is commonly encountered in many zone electrophoresis protocols when the loading of samples in solutions differing from the BGE is recommended. ITP will often occur transiently in the loading band leading to a concentration of some analytes at the front or rear of the loading band.

Electrophoretic Separation Media

Electrophoresis can be performed in free solution, but thermal and diffusional mixing are usually too great to give satisfactory resolution of the components. It has long been recognized that it is usually necessary to use some type of static support in order to contain the background electrolyte, contain the sample and limit diffusion. The primary function of the stabilized support media is to limit the dispersion that results from convective disturbances. The stabilization should not change the mobility of the ions significantly provided that neither absorption onto the support occurs nor do large analytes become physically trapped.

Over the years a large number of supports have been used as stabilizing media, but relatively few satisfy all the criteria for the ideal support (Figure 8). These criteria are a reproducible structure, good mechanical strength, ease of formation into appropriate shapes, chemically inert to both the electrolyte and the analytes, no thermal degradation and minimal background in the detection processes. The earliest support was probably cellulose in the form of sheets of laboratory filter paper. Kunkel and Tiselius published the classic study on paper electrophoresis in 1951. Cellulose acetate membranes have large pores and do not retain proteins either chemically or physically. It is the preferred membrane for serum protein separations.

Figure 8 Common stabilized media used in electrophoresis.

Slab Gel Electrophoresis

Subsequently naturally occurring gels were investigated particularly for the separation of plasma proteins. Agar gels, especially in the form of the highly purified subunit agarose, are still a popular medium for protein separations. Agar forms gels at relatively low concentrations, but due to its high number of sulfate and carboxylic groups it generates a significant EOF. The sulfate and carboxylic fraction can be removed chemically to leave agarose, which has much reduced EOF and gives a better resolution of proteins. The gels are formed as slabs by pouring a liquid gel into a mould and letting it set before placing in an electrophoresis system.

In 1955 Smithies, modifying an earlier method, introduced the technique of starch gel electrophoresis and its superior resolving power for proteins was immediately apparent. The starch was derived from hydrolysed potato starch and poured to a thickness of 5–10 mm. In addition, the pores in the starch gel matrix are close to the molecular size of proteins so that in this form electrophoretic movement is accompanied by some molecular sieving, but the effect was irreproducible.

In 1955 Raymond and Weintraub introduced a synthetic polymer gel made from the monomer polyacrylamide, as a replacement for starch. Polyacrylamide gels have many advantages over starch being tougher, more flexible, naturally clearer and chemically inert. Acrylamide gels are formed by the polymerization of the monomer acrylamide in the presence of an *N,N'*-methylenebisacrylamide (BIS). The reaction requires initiators and a catalyst (cross-linking reagent). Commonly used catalysts are ammonium or potassium persulfate (for chemical polymerization) or light and riboflavin (for photopolymerization). A common initiator is *N,N,N',N'*-tetramethylethyldiamine (TEMED). The polymerization should be performed at above 20°C to prevent incomplete polymerization. The reaction takes place via vinyl polymerization and gives a randomly coiled gel structure. The concentration of polyacrylamide can be varied over a wide range without making the gels unmanageable. The pore size can also be controlled exactly by varying the amount of BIS used in the polymerization (Table 3) so the precision of the molecular sieving is enhanced.

The use of such gels for electrophoresis is commonly referred to as polyacrylamide gel electrophoresis (PAGE). In addition to the tight control of pore size other advantages of polyacrylamide gels compared to starch gels are that the adsorption of macromolecules to polyacrylamide is negligible, there is little EOF associated with polyacrylamide and strong,

Table 3 Effect of cross-linking on pore size of acrylamide gels

Percentage of <i>N,N'</i> -methylenebisacrylamide (BIS)	Molecular weight range resolved
5	50 000–300 000
10	10 000–100 000
15	~ 5 000

but thin, transparent gels can be cast permitting faster separation. A disadvantage is that the monomers are toxic and need to be handled with caution.

Development of the gel system followed rapidly. In 1964 Ornstein and Davis simultaneously introduced discontinuous (DISC) electrophoresis, which improved both the solubility of the proteins in the gel as well as improving the resolution. In DISC electrophoresis the gel is formed in two sections, a stacking gel and a resolving gel. The resolving gel has small pores filled with a buffer of pH 8.8 high mobility buffer (e.g. 2-amino-2-hydroxymethylpropane-1,3-diol-hydrochloric acid (TRIS-HCl)) and a large pore stacking gel contains a buffer of about pH 6.8. The sample is loaded at approximately pH 8.8. These conditions induce the proteins to migrate according to isotachopheresis through the stacking gel, then stacked at the interface with the resolving gel before slowly destacking and resolving as they pass through that gel.

The size and shape of macromolecules complicates their separation, so special buffer/electrolyte conditions are employed. Non-dissociating (native) buffer systems, as described earlier for DISC electrophoresis, are used to separate the native forms of proteins and double-stranded DNA. Dissociating (denaturing) buffer systems can also be used, for example, double-stranded DNA is denatured using urea, formamide, sodium hydroxide or intercalating agents such as ethidium bromide prior to application to the gel.

Although it is appreciated that the use of gels not only aided the electrophoretic separation, for macromolecules it also introduced a size-sieving effect equivalent to gel filtration in chromatography. This can be used to 'size' molecules, particularly proteins. So if the conditions are correct and if the pores are of the appropriate dimensions could PAGE also be used to determine the molecular weight of proteins?

Sodium Dodecyl Sulfate–Polyacrylamide Gel Electrophoresis (SDS–PAGE)

Unlike DNA, proteins exhibit considerable differences in their overall charge-to-mass ratios.

Depending on pH, their charge can range from basic to anionic and from hydrophobic to hydrophilic, and their shapes can vary from globular to linear with varying degrees of cross-linking. Shapiro introduced electrophoresis in the presence of sodium dodecyl sulfate (SDS) which is an anionic surfactant that is used to solubilize proteins. Proteins are first denatured with SDS which binds to the hydrophobic backbone of proteins in a regular fashion. Almost regardless of the type of protein, 1.4 g of SDS binds to 1 g of protein and solubilizes it. In addition, the charge on the SDS overwhelms the charges on the protein. The degree and type of denaturing can also be enhanced by using SDS solutions which also contain urea and/or a thiol such as dithiothreitol (DTT). The complex is now more or less linear with an overall negative charge so all proteins migrate in a single direction. The denatured unknown proteins are then electrophoresed by PAGE in a buffer system incorporating 0.1% SDS. By running a series of known standards in a parallel lane, the technique can be used to derive molecular weight information since there is a fixed relationship between the relative migration distance of SDS-protein complex and the molecular weight of the native protein.

Pulsed Field for DNA

Agarose gel electrophoresis is the method of choice to resolve DNA restriction fragments provided the fragments are between 1000 and 23 000 bp in size. For larger fragments, Schwartz and Cantor developed the technique of pulsed field gel electrophoresis (PFGE) in 1984. In PFG DNA fragments greater than 23 kbp are forced to change their structure during electrophoresis by pulsing the applied field so causing the molecules to relax and expand regularly and thereby interact with the gel pores. DNA molecules up to the size of chromosomes can be electrophoresed in this manner, but the separation can take many hours or even days.

Basic Instrumentation for Electrophoresis

Instrumentation for performing electrophoresis is both cheap and simple. It consists of a means of generating a DC voltage, a buffer tank which also has some means of holding the separation media between the two electrodes. A schematic diagram of such a horizontal tank is shown in **Figure 9**. Such an apparatus needs to be levelled in order to prevent the electrolyte from siphoning from one end to the other and so disturbing the electrophoretic resolution. The

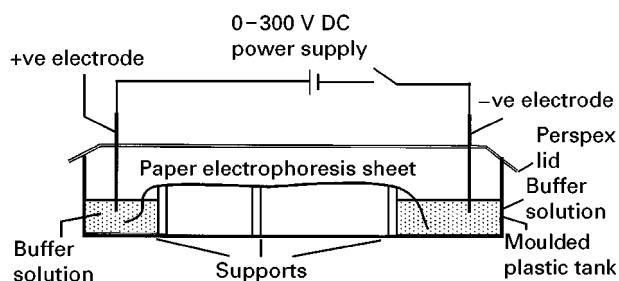

Figure 9 Schematic diagram for a paper or membrane electrophoresis system.

power supply can be as simple as a 12 V battery, but is usually a mains electricity transformer delivering 100–500 V DC. The required voltage is selected by a digital potentiostat combined with a polarity switch, the run time can also be selected digitally. Usually there are controls to select constant voltage, constant current and constant power modes of operation. If the instrument's designed maxima in any of these modes are exceeded there is a cut-off (safety) trip. Electrical power is usually taken to the electrophoresis tank via a pair of suitably rated copper cables. The tank itself is typically made of a waterproof and electrically insulated plastic material covered with a lid to prevent evaporation and contamination of the system. The size of the tank will depend on the type of separation being undertaken and can range from as small as 100 mm square to as large as 500 mm × 300 mm. The tank is divisible into a number of compartments with plastic spaces. The outer two hold the electrodes. The electrodes are usually made of fine platinum wire connected through the tank wall to the leads from the power supply. Suitable safety devices are included in the tank to prevent operator accidents, for example the power is cut-off if the lid is removed.

With the development of gel electrophoresis system new forms of apparatus were developed. It is necessary to mount and support the gel between the two electrode chambers so that the only electrical connection is via the gel. Electrical contact between the gel and the electrolyte is made either directly or by a wick of some description. Gels can be of many sizes depending on the separation distance required. Tubes of gel with an internal diameter of 1–5 mm and 50–250 mm in length can be prepared, but slab gels, either used vertically or horizontally, are much more common. Vertical slab gels are cast by pouring liquid gel into the space between a pair of glass plates separated by thin spacer strips positioned at the edges and bottom. The plates are clamped to prevent leakage. The thickness of the gel depends on the thickness of the spacers, which can be from 50 µm to 5 mm

depending on the application. At the top, a sample well comb is used to create indentations into which samples can be placed. Following the setting and/or polymerization of the gel, the comb is carefully removed and sample(s) (5–10 μL) are loaded into each well. Molecular weight markers, known proteins or DNA fragments, are usually applied to one or both of the two outer lanes. The upper and lower buffer chambers are then filled and the system is connected to the power supply. Appropriate voltages are selected and the power is turned on for the appropriate time. In order to monitor the progress of the separation it is common practice to include a marker dye in the sample. When the dye reaches the end of the gel (normally after some hours) the power is disconnected. The buffer is drained and the gel removed from between the plates prior to staining or blotting (Figure 10).

As well as vertical formats it is also possible to run horizontal slab gels either completely immersed in electrolyte solution (so-called submarine gels) or with suitable wetted connectors.

Although it is relatively easy to construct your own low-voltage electrophoresis system, especially the tanks, systems are available from a large number of suppliers, such as Amersham-Pharmacia, Bio-Rad, Hoeffer, and so on. The cost of commercial systems range from a few hundred pounds to about £5000 depending on size, configuration, maximum voltage and whether or not cooling systems are included. Today, even the preparation of gels can be simplified. Premixed reagents are available to simplify the production of reproducible gels and it is

now possible to buy precast gels which only need to be mounted in a suitable holder.

Detection Methods in Electrophoresis

At the end of an electrophoretic run the analytes are distributed over a two-dimensional surface or included within a thin three-dimensional gel. With only a few exceptions, the majority of analytes will not be visible to the naked eye and many methods for both the detection, localization and quantitation of separated bands and spots have been developed.

Direct optical methods can be applied in some cases. For example, the bands of haemoglobin separated by electrophoresis on a nitrocellulose membrane can be observed directly. In some cases placing the paper or gel on a ultraviolet (UV) lightbox or under a UV lamp can reveal UV absorbing bands, UV fluorescence bands and sometimes bands that quench the background UV fluorescence.

Since the analytes are often trapped within a fragile gel, then some means of extracting them from that matrix often is necessary before a visualization method can be applied. For this purpose, one of the blotting techniques is applied. Blotting involves the transfer of the sample bands or spots from a gel to a sensitized membrane using either physical or electrical mechanisms. Nitrocellulose, Nylon or polyvinylidene difluoride (PVDF) are the most common membranes because they provide hydrophobic surfaces on which proteins readily adhere, as well as being physically strong. In 1975 Professor Ed Southern described the first of these procedures, which is commonly called Southern blotting, for use with DNA. In this method, diffusion of DNA from a continuously wetted electrophoresis gel to a membrane is achieved by pressure applied to a sandwich of wetted wick-gel-membrane-stack of blotting paper (Figure 11). The DNA in the gel is carried into the membrane that binds the DNA giving a faithful image of the original gel. The process takes up to 24 h but can be speeded by using a vacuum to draw the buffer through the gel.

The same procedure when applied to RNA is playfully, but consistently, called a Northern blot. In the same vein a Western blot is any procedure for the transfer of proteins from a gel to a membrane. Although with proteins this usually involves their electromigration linked to immunodetection with appropriate antibodies. Transfer using electrophoretic techniques applied across the thickness of the gel is generally faster than capillary action. The gel, containing protein or DNA, clamped next to the blotting membrane in a cassette, is then immersed in a buffer solution between two electrodes.

Figure 10 Schematic diagram of a vertical gel electrophoresis system.

Figure 11 The principles of two types of blotting: (A) Southern blotting and (B) semi-dry Western blotting.

Applying a voltage causes the proteins/DNA to migrate to the membrane. If filter papers wetted with buffer are used instead of buffer, then this is called semi-dry blotting. Once the analytes have been stabilized on the membrane they then can be probed in order to detect the analytes (this is discussed further below).

If separations were performed on sheets or have been blotted, then the position of the analytes can be determined by the following methods. If radioactivity has been incorporated in the analytes prior to electrophoresis, then the position of the analytes on the membrane can be determined by autoradiography. The membrane is placed with the gel in contact with photographic film and left to expose (hours to weeks) in the dark and possibly the cold. The film is developed and the position of the analytes is revealed by the exposed parts of the negative. If required, the original membrane or gel can then be overlaid on the negative and the radioactive spots obtained by cutting-up the gel followed by elution and scintillation counting.

It is often necessary to reveal analytes of interest using some form of derivatization. This may mean spraying the blot or membrane with a specific reagent that chemically reacts with the analyte to give a coloured product, for example, ninhydrin gives a purple product with amino acids, peptides and some proteins. For macromolecules it is more common to refer to this process as staining using either appropriate dyes or other reagents. Proteins can be detected in gels with a large number of dyes of which the most common is Coomassie brilliant blue which can detect as little as 0.3 μg of protein in a spot. DNA is usually detected using the fluorescent intercalating dye ethidium bromide. The process involves staining fol-

lowed by destaining to remove unbound dye and then fixing of the image. Both proteins and DNA can react with silver ions to form black silver precipitates. This method is some 100 times more sensitive than the current dye methods and can detect as little as 2 ng of some proteins.

The above methods are relatively non-selective, although for simple mixture comparisons against standards they may be sufficient to identify proteins. More specific methods of detection include zymography and immunoelectrophoresis. Early methods include immunodiffusion in which an antiserum is allowed to diffuse into a gel so generating precipitin bands and rocket electrophoresis. Today the most common application of immunotechniques is in Western blotting with immunodetection; this is so common that many workers believe it is Western blotting. After blotting, the immobilized proteins are probed with primary antibodies specific for the protein(s) of interest. This is followed by an enzyme-linked second antibody directed against the first antibody, for example sheep anti-mouse immunoglobulin G (IgG). The enzyme is usually a peroxidase or alkaline phosphatase. The blotted membrane is first soaked in a solution to block non-specific binding sites followed by incubation with a suitably diluted solution of the first antibody for up to 1 h. The antibody solution is then washed off before incubating with the secondary antibody complex. Again, following washing, the proteins are revealed by incubation with an appropriate visualization reagent. Depending on the antibodies available such methods can be very selective and also very sensitive.

Finally, the most modern methods of both detection and protein characterization involve mass spectrometry and are dealt with below.

Quantitation

The above methods are usually indirect and qualitative, so if you wish to obtain quantitative analytical data from electrophoretic separations or blots it is necessary to determine the area of the separated bands. The amount of analyte present is related to the area of the spot or band when compared to standard solutions. The areas of bands can be obtained using densitometry or digital image analysis to scan the gels or blots. However, even modern densitometry is only semi-quantitative with coefficients of variation of 10–20% at best.

Two-dimensional Separations

Since traditional electrophoresis is usually planar, more than one separation dimension can easily be

combined. The use of orthogonal techniques increases the resolution of the systems in proportion to the product of the resolution of each dimension assuming the two modes are truly orthogonal. For example, separations that each give 10 bands in a single direction/mode will theoretically give 100 spots if combined. The sacrifice is, of course, speed, it will take twice as long, and increases the number of manipulations involved.

Early work such as peptide mapping often used high-voltage electrophoresis in the first dimension and then chromatography in the second. For a decade or more this was the standard method for generating tryptic maps for studies on such areas as haemoglobin variant analysis. However, each sample would take nearly two days to run, a day for each dimension.

The most popular two-dimensional electrophoretic method is the combination of IEF with SDS-PAGE. O'Farrell and Klose independently introduced this system in 1975. In O'Farrell's original system isoelectric focusing in ampholytes was used in the first dimension and the resulting tube gel was then carefully attached to a slab gel followed by running in the SDS-PAGE mode. This method was able to separate up to 1000 protein spots from a protein extract of a tissue. However, the system required considerable expertise to use due to the variation in the IEF step; many workers found it irreproducible. With the development of immobilized IPGs the ease of operation of the IEF component was, as already discussed, greatly improved and relatively simple two-dimensional systems are now available commercially. For gels of 250 mm × 250 mm up to 3000–4000 protein spots can be revealed by silver staining from extracts of tissues such as liver. In this mode electrophoresis is probably the separation technique with the highest resolution available to the modern researcher.

Proteome analysis (proteomics) is a major new field of biomedical research. The proteome is defined as the total complement of proteins found within an organism, cell, tissue or biofluid. While the human genetic code will soon be known, its relationship to cell function will only be ascertained by advances within proteomics. For example, DNA sequences are not predictive of post-translational modifications such as glycosylation within the encoded proteins. Proteomics is the method of qualitatively determining this large number of proteins. It combines the high-resolution two-dimensional electrophoretic techniques mentioned above with digital image analysis, some elements of HPLC and modern mass spectrometry plus on-line bioinformatics to search databases. For example, two-dimensional proteome maps can be produced for a tissue such as liver and then digitally compared with the same tissue taken

from a diseased subject. The differences in the complex pattern, which may contain 1000+ spots, can be highlighted automatically and then mass spectrometry either of the MALDI-ToF and/or electrospray variety can be used to identify the variant proteins. By using such approaches it is now possible to identify known proteins using bioinformatic tools over the Internet in a matter of minutes, and to determine the structure of an unknown protein may only take a day or two.

Fields of Application

Although almost every class of molecule, especially those of a biochemical nature, has been separated by planar electrophoretic methods few are now done so. Early textbooks on electrophoresis detail separations of amino acids, sugars, purines and pyrimidines, nucleotides, some drugs, carboxylic acids, vitamins, and so on, but today's analyst would now use HPLC or capillary electrophoresis for such quantitative studies. Only for protein and DNA molecules is planar electrophoresis still the method of choice? Electrophoretic methods are used for qualitative and quantitative separation of proteins in clinical samples, biotechnological production and quality control, genomic and proteomic studies.

Traditional Planar Electrophoresis – Conclusions

This is still a basic tool in biochemistry and biomedicine since it is simple and often very cheap, parallel analyses are usual and so although any one run is slow, the many bands can be run at the same time so overall throughput is reasonably high. With the appropriate detection techniques, selectivity and sensitivity can be very good. By using thick media electrophoresis the technique can be made at least semi-preparative. Finally, in two-dimensional formats (IEF-SDS-PAGE) electrophoresis probably gives the highest resolution known in separation science.

However, perceived disadvantages are that it offers only low resolution in one-dimensional separations and the results are at best only semi-quantitative. Since it is difficult to use high voltages, it is seen as a slow technique made slower by the fact that detection is nearly always off-line.

Nevertheless there is a wealth of experience with the hundreds of available methods and probably millions of analytes are separated every day using traditional electrophoretic methods. Many of these analyses go unnoticed, for example the routine examination of serum proteins in clinical biochemistry laboratories throughout the world and the hundreds of daily runs sequencing DNA and so on in molecular

biology laboratories. However, research still continues into the technology and ultra-thin gels for DNA sequencing are giving excellent results and automated equipment for use with proteomics both in the electrophoresis stage and the sample isolation stage is being developed. Even after 100 and more years there is still much life in this technology.

Capillary Electrophoresis (CE)

For 40 years it had been appreciated that the excessive Joule heating that developed when high voltages were used to speed-up electrophoresis caused many of the technique's disadvantages. These disadvantages ranged from simply boiling the buffer solutions through to instrument fires and even electrocution. Many attempts were made to overcome the physico-chemical problems that degraded the separations. For a time in the 1960s and 1970s high-voltage electrophoresis systems operating at up to 10 kV were available. They were usually very large pieces of equipment that used large sheets of chromatography paper for the separations and required substantial pumped water cooling systems to remove the heat generated. Other equally complex systems with rotating Pyrex tubes to equalize the heating effects were also developed.

As with many problems, the solution when it came was very simple. In 1981 Jørgenson rationalized the problem to one of increasing the rate of cooling by substantially increasing the surface-to-volume ratio of the electrophoresis buffer. This, he showed, was readily achieved by performing the electrophoresis in small-bore capillaries. In a classic series of papers in that year Jørgenson and Lukacs described spectacular separations of peptides using zone electrophoresis in glass capillaries of 75 μm internal diameter using voltages of up to 30 kV with electrokinetic injection and fluorescence detection. This format enabled the Joule heating that normally degrades the resolution by thermal mixing to be efficiently dissipated. In addition, this new format used the significant electroosmotic (EOF) flow of the background electrolyte in the capillaries to separate cation, anions and uncharged molecules simultaneously with all analytes usually going towards the cathode where a single on-line detector was placed.

This discovery led to the development of a new form of analytical separation instruments that was very equivalent in its operation to HPLC. Most of the major HPLC instrument manufacturers had by the end of the 1980s introduced CE systems with varying degrees of sophistication. There was also considerable optimism that CE was going to replace HPLC for analytical separations. Ten years later only three

Figure 12 The configuration of a simple capillary electrophoresis (CE) instrument.

companies are still marketing complete CE instruments.

Today CE is characterized by its ability to resolve, using applied DC voltages giving field strengths up to $500 \text{ V}^{-1} \text{ cm}^{-1}$, the components of complex aqueous samples with very high resolution ($N > 250\,000$) analysing less than 10 nL of sample with analytical precision. To maintain efficiency, detection (UV, fluorescence) is nearly always on-line, i.e. across a window burnt into the polyimide coating of a silica capillary. Detection at the end of capillary can be achieved using electrochemical detectors or more usefully mass spectrometry.

A typical CE instrument consists of a capillary, detector, high-voltage power supply, recording device (**Figure 12**). The capillary used is made of fused silica and externally coated with a thin layer of polyimide, to make the capillary flexible. The capillary is usually about 375 μm outside diameter and 10–150 μm inside diameter with 50 and 75 μm the more usual. There is no set capillary length, although in commercial instruments there are minimum lengths which can be used, and this is usually dependent on the position of the detector. To allow detection a small section of polyimide coating has to be removed making a weak point in the capillary.

In CE electroosmotic flow (EOF) is a positive benefit, unlike in traditional electrophoresis systems. The silanol groups on the inner surface of the silica capillary are negatively charged above approximately pH 3 so cations build up near the silanol groups to maintain the charge balance. When the potential difference is applied to the capillary these cations are attracted towards the cathode, and they drag the bulk solution along with them (**Figure 13**).

The magnitude of the EOF is dependent on the surface charge of the capillary silanol groups, which varies with pH so that the EOF velocity increases with increasing pH. The flow profile of the EOF is different to the solvent flow profile found in HPLC. The laminar or parabolic flow produced by

Figure 13 The electroosmotic flow (EOF) profile in a silica capillary electrophoresis (CE) capillary.

a liquid chromatography pump is due to the shear force at the capillary walls. In CE there is no pressure drop and therefore a flat flow profile is produced giving very much sharper peaks. In addition, at $\text{pH} > 6$ the EOF will be of sufficient magnitude to carry all the analytes regardless of their change in the same direction, this will only happen if the magnitude of the EOF is greater than the electrophoretic mobilities of the anions. The EOF will also carry neutral molecules along, although it cannot separate them. Since everything is moving in one direction an on-line detector can be placed at the cathodic end of the capillary. The output from a CE system is therefore very similar to that from HPLC systems – a series of peaks with baselines drawn in (if required) and areas of peaks calculated.

The present generation of commercial CE instruments is capable of unattended operation and features auto-injection using a variety of modes, integration and spectral analysis in a manner analogous to HPLC. CE has become widely available and the technology is now included in a number of other instruments such as a clinical protein analyser (Beckman Paragon) and in a DNA sequencer (PE-ABI 3700). In both of these instruments a large number of capillaries are operated in parallel in order to increase sample throughput, but the end users buys an instrument dedicated to a specific application not a CE instrument.

Modes of operation for CE CE is generally recognized as the description appropriate for the whole field of this separation science. CZE stands for capillary zone electrophoresis, in which ions are separated according to their mobility in free solution. This is the most frequently used separation mode option available within CE. A subtype of CZE is capillary ion analysis (CIA), which is used to determine simple ion species in aqueous solution rapidly. The other forms of electrophoresis described earlier such as isoelectric focusing and isotachopheresis can also be performed in a capillary format and are called cIEF and cITP, respectively. MEKC, sometimes called MECC – micellar electrokinetic capillary chromatography – is a separation mode introduced in 1984 by Terabe which allows the separation of neutral molecules by

their differential partition into charged micelles formed from detergents incorporated into the CE electrolyte. MECC can also be viewed as a subclass of CE methods involving complexation and inclusion using additives to the background electrolyte. Another separation mode is capillary gel electrophoresis (CGE), which was introduced by Cohen and Karger in 1988. This offers DNA and SDS-PAGE separations in a capillary, but with advantages in terms of speed, quantitation and ease of automation. The filling of capillaries with gels has now been supplanted by the use of entangled viscous polymer solutions to separate DNA. A recent development is the use of EOF to drive eluent through a capillary packed with HPLC stationary phase. This is termed capillary electrochromatography (CEC) and some very high efficiencies for neutral compounds have been demonstrated using this technique. CEC is performed on standard CE instrumentation, but has the added advantage that the eluents used are more readily interfaced to MS than is CE.

There has been a great deal of debate about the benefits and disadvantages of CE and it is worth touching on a few points here. The immediate attraction of CE for many analyses is its high efficiency giving the resolution needed to analyse complex samples and mixtures of biomolecules. CE can readily achieve separation efficiencies of orders of magnitude greater than those obtained by HPLC. From 100 000 to 250 000 theoretical plates per capillary is common, while up to 30 million have been reported for the CGE of oligonucleotides. Such efficiencies mean that 'isocratic' CE is capable of improving on the resolution obtained by both isocratic and gradient HPLC. **Figure 14** shows the separation of the complex array of metabolites and exogenous compounds excreted in normal human urine. A simple MEKC separation is shown resolving over 60 peaks in about 10 min. CE separations are simpler both in operation and equipment, and potentially much faster and quantitative. Thirty per cent more peaks have been observed resolved by CE compared to gradient HPLC under similar sample detection conditions. By using a high potential in short, narrow capillaries very fast assays using CE are possible. Many small ions can be resolved in only a few minutes. So-called short-end injection is also useful for high-speed separations. Such runs combined with minimal sample preparation means that some assays can take less than 1 min by CE. Mass sensitivity in CE is superb, as proved in the many elegant experiments that have determined various components in a single living cell. However, the concentration sensitivity is about one order of magnitude lower than in HPLC for the same detector. This is because the probed volumes

Figure 14 High-resolution separation of UV absorbing components of human urine separated by MEKC with detection at 195 nm.

are correspondingly lower, e.g. UV detection samples across a 50 μm capillary in CE compared to 10 mm in HPLC. There is much activity in detector development to address the problem of sensitivity. Laser-induced fluorescence (LIF) has been studied widely and promises to bring detection limits down to the single molecule level for appropriate fluorophores. LIF detection is now commercially available. CE-MS with electrospray ionization has proved to be a powerful technique with applications to structural studies of large biomolecules as well as small ions, and there is good concentration sensitivity using capillary isotachopheresis as the separation mode.

Applications Clearly CE is very good for separating charged species whether small molecules or macromolecules. It is necessary to operate in MECC mode to separate neutral molecules such as drugs. There are now some 5000 publications describing separations of some 10 000 compounds by CE. Charged and neutral compounds are all easily separated but there are too many examples in the literature to even attempt to describe them here. The high resolving power of CE is such that it can readily resolve enantiomeric compounds. The most commonly employed method is to include cyclodextrins into the electrolyte. β -Cyclodextrin is the most readily available compound, but recently sulfated derivatives of β -cyclodextrin have been shown to give separation of chiral compounds with spectacular resolution between the enantiomers. Oligonucleotides have pro-

ved to be readily separated using entangled polymeric additives such as hydroxyethylcellulose in the electrolyte to increase its viscosity and therefore gel-filtration effects. While the potential for quantitation shows enormous promise for proteins, there are several problems which remain to be overcome. Wall interactions degrade resolution and at worst lead to total adhesion of proteins to negatively charged sites on the silica capillary. Strategies to minimize this include covalent bonding to give coverage of the surface by hydrophobic groups, and dynamic coating using solution-phase additives.

In comparison to HPLC, CE achieves better resolution than both isocratic and gradient HPLC using simpler instrumentation. CE is not a preparative technique, although it has been used as a micropreparative system to isolate very small amounts of protein for sequencing. It is less sensitive than HPLC by about an order of magnitude. There is little difference in terms of quantitative data and analytical precision. Sample preparation probably needs to be better controlled and understood than for HPLC. At present, CE instrumentation is more expensive than HPLC, although running costs are considerably lower. CE uses much less sample and reagents than HPLC. Waste disposal problems are considerably reduced.

CE has now found a role in many laboratories and offers useful complementary separations to HPLC. It is clearly an established technique with a long-term future in the separation sciences.

EXTRACTION

Introduction

Extractions are common in the world around us. Each time we brew a cup of tea or a pot of coffee, and each time we launder our clothes, we're performing a chemical extraction process. Perhaps because of this familiarity, extraction processes in chemical laboratories are often not fully appreciated, or fully understood. Quite simply, an extraction is the process of moving one or more compounds from one phase to another. Yet behind this simple definition lies a great deal of subtlety: separations are contrary to thermodynamic intuition, because entropy is gained through mixing, not separation; extraction methods are developed based on a drive towards equilibrium, yet the kinetics of mass transfer cannot be ignored. Such a list of physical chemical nuances provides the basis for this chapter on the fundamentals of chemical extractions.

Extractions are carried out for a variety of reasons, for example when distillation is either impractical (e.g., distillations are favourable when the relative volatility of the compounds to be separated is greater than about 1.2) or is too expensive, to isolate material for characterization, to purify compounds for subsequent processing, etc. Extractions can be classified according to a number of schemes:

- analytical versus preparative (depending on the quantity of pure compound to be separated);

- batch versus continuous (depending on the mode of feeding the material to be separated into the extraction apparatus);
- based on the physical principles involved (is the extraction strictly based on partitioning, or are adsorption or other processes involved?);
- based on the types of phases involved (so called liquid-liquid extraction, gas-solid extraction, supercritical fluid extraction, etc.).

Perhaps the biggest recent advances in the field of chemical extractions have taken place in the petroleum, nuclear, and pharmaceutical industries. The understanding and practise of extraction lies at the crossroads of analytical, inorganic, organic, and physical chemistry, with theoretical and applied chemical engineering. Yet the fundamental physico-chemical principles involved are the same. Because of the author's background, this chapter presents a description of the fundamental basis for chemical extractions and an overview of extraction techniques with a slant, or emphasis, towards the analytical chemists' perspective.

In general, the extraction process occurs as a series of steps. First the extracting phase is brought into intimate contact with the sample phase, usually by a diffusion process. Then the compound of interest partitions into or is solubilized by the extracting solvent. With liquid samples this step is generally not problematic. However with solid samples, for the compound being extracted to go into the extracting solvent the energy of interaction between the compound of interest and the sample substrate must be overcome. That is, the material's affinity for the extracting solvent must be greater than its affinity

Table 1 Summary of selected extraction techniques by phases involved and the basis for separation

Extraction technique	Sample phase	Extracting phase	Basis for separation
Liquid-liquid extraction	Liquid	Liquid	Partitioning
Solid-phase extraction (and microextraction)	Gas, liquid	Liquid or solid stationary phase	Partitioning or adsorption
Leaching	Solid	Liquid	Partitioning
Soxhlet extraction	Solid	Liquid	Partitioning (with applied heat)
Sonication	Solid	Liquid	Partitioning (with applied ultrasound energy)
Accelerated solvent extraction	Solid	Liquid	Partitioning (with applied heat)
Microwave-assisted extraction	Solid	Liquid	Partitioning (with applied microwave irradiation)
Supercritical fluid extraction	Solid, liquid	Supercritical fluid	Partitioning (with applied heat)
Purge-and-trap	Solid, liquid	Gas	Partitioning
Thermal desorption	Solid, liquid	Gas	Partitioning (with applied heat)

for the sample. Finally the extracting phase (containing the compound of interest) must diffuse back through the sample, separate into a distinct phase, and be removed for subsequent processing. With proper selection of the extracting solvent this final step is generally not difficult, though the formation of emulsions must be avoided with liquid samples.

As previously mentioned, extractions (and other separation processes) are contrary to the principles of thermodynamics and work must be applied to overcome these thermodynamic constraints. Perhaps this has been expressed most eloquently by Giddings:

It seems enigmatic that we often struggle so hard to achieve desired separations when the basic concept of moving one component away from another is inherently so simple. Much of the difficulty arises because separation flies in the face of the second law of thermodynamics. Entropy is gained in mixing, not in separation. Therefore it is the process of mixing that occurs spontaneously. To combat this and achieve separation, one must apply and manipulate external work and allow diffusion in a thermodynamically consistent way.

This external work is often applied as heat (temperature), which results in faster kinetics, decreased solvent viscosity and surface tension, increased solute solubility and diffusivity, and aids in overcoming interactions between the solute and the sample. A general analytical chemistry textbook (Peters, Hayes, and Hieftje (1974) *Chemical Separations and Measurements: Theory and Practice of Analytical Chemistry*. Philadelphia: Saunders) further describes the extraction process and areas for improvement:

If two compounds are to be separated, we must, somewhere along the line, get them into two dif-

ferent and separable phases ... At the heart of any chemical separation are the processes of (1) phase contact and equilibrium and (2) phase separation. These steps occur in all separation techniques, and a key in understanding a given method is the identification and classification of the steps according to the nature of the phases involved and the mechanism of phase contact and separation. Similarly, if a particular method of separation is to be improved, these are the only processes worth adjusting.

Using this discussion as a framework we can classify various extraction techniques according to the phases and applied work (or the basis of separation), as shown in **Table 1** for several selected extraction techniques.

The progress of an extraction is graphically depicted in **Figure 1**, which is a plot of the extraction yield (e.g. mass extracted) versus the progress of an extraction (e.g. solvent volume, time, equilibrium stages, etc.). This plot is generally asymptotic and consists of two regions. The initial, more steeply sloped region is the equilibrium region. This is the area where the effects of solute partitioning and solubility exist.

Figure 1 Plot of the relative amount (mass) extracted as a function of extraction progress (e.g. solvent volume, time, etc.). Three regions are defined: an equilibrium region dominated by solute partitioning, a diffusion region controlled by solute diffusion, and a transitional region.

As the extraction progresses it transitions into a region predominated by solute diffusion as well as the necessity for the solute to overcome effects such as solute-sample matrix interactions.

Preliminary Requirements

Chemical samples requiring extraction are composed of the compound of interest and the sample matrix, which may contain interfering species. Prior to choosing an extraction method, knowledge must be gained about the structure (including functional group arrangement), molecular mass, polarity, solubility, pK_a , and other physical properties of both the species of interest and potential interfering compounds. Constraints specific to the sample and the solvent must be considered, and the resulting concentration and desired degree of purification must be taken into account. This section discusses these preliminary considerations. Solvent-specific considerations and the roles of solute solubility, partitioning, and diffusion will subsequently be addressed.

Terminology

In discussing the fundamental processes in extraction, it is important to keep the appropriate terminology in mind. Extractions occur by the distribution of a compound between two immiscible phases. The mixture containing the component(s) to be separated is called the *feed* or *sample*. The extracted compounds of interest are described by several terms, including *solute* or *analyte*, while the phase left from the feed after being contacted by the extracting phase is the *raffinate* (generally used for liquids) or *residue* (solids). The *solvent* is the immiscible extracting fluid added to the process for the purpose of extracting solutes from the feed. One key feature is the lack of mutual solubility between the feed and the extracting solvent. Usually less than 10% solubility of the solvent in the feed is desired. Because phase separation is a defining parameter in chemical extractions, fluid flow is important for transporting the solute both through the sample (facilitating diffusional mass transfer by maintaining a concentration gradient at the interface between the phases) and through the system. Thus the solvent must be a gas, liquid, or supercritical fluid. (Solid extracting phases do not serve to move the extracted material through the system. In extraction techniques such as solid-phase extraction or matrix-solid-phase dispersion the solid phase assists in removing the solute from the feed, but fluid solvents are required to remove the solute from the solid phase.) During an extraction process, each equilibrium event is termed a *stage*; hence a theoret-

ical (or equilibrium) stage is a mechanism, or extraction region, where the immiscible phases are brought under equilibrium conditions then physically separated. The placement of the extraction stage can help define the extraction process. For example, a *cross-current* extraction is composed of a cascading series of states where the raffinate is brought into a subsequent stage and contacted with fresh solvent. In a *countercurrent* extraction, the solvent and feed enter from opposite ends of the system, and these two immiscible phases pass each other in opposing streams.

Batch and Continuous Extraction Modes

One means of classifying extractions is based on the mode of operation, batch or continuous and static or dynamic. The terms batch and continuous refer to how the sample (feed) is placed into the system. In batch extraction processes the entire material to be extracted is loaded into the extraction device. In the case of continuous extractions the feed is continuously introduced into the extraction device. Static and dynamic describe the exposure of the two phases. In the static mode the extracting solvent and the feed are brought into contact and allowed to commingle for a prescribed period before the phases are separated, while dynamic extractions occur by continuously passing clean (whether fresh or recycled) extracting solvent through the sample.

Most analytical extractions are performed using a batch-wise process. This mode is used when the distribution ratio (i.e., the ratio of the solute between the two phases) is high, favouring the extraction solvent. With batch extractions few stages are needed to achieve quantitative results, though phase separation has to occur before the extraction is complete. Batch extractions can occur in static or dynamic modes, or in some combination. For example, the familiar Soxhlet technique for extracting solid samples, depicted in Figure 2A, is considered a batch process with discontinuous solvent infusion, that is involving both static and dynamic modes.

Similar extractors for laboratory-scale liquid-liquid extraction, again shown in Figure 2, are also based on distilling the extracting solvent with subsequent condensation. The condensed solvent passes through the sample solution to be extracted, phase separation occurs, and the extracting solvent flows back into the receiving flask for redistillation. Design considerations account for the solvent density. The glassware shown in Figure 2B is representative of aqueous-organic extractions using heavier-than-water solvents, while Figure 2C illustrates an apparatus for use with lighter-than-water solvents.

Figure 2 Laboratory glassware for performing (A) Soxhlet extraction, (B) liquid-liquid extraction with extracting solvents more dense than the liquid solvent, and (C) liquid-liquid extraction with extracting solvents less dense than the liquid sample.

When batch-wise extraction procedures are used for studying physical chemical properties, such as solubility or distribution ratios, special care must be taken, especially when aqueous phases are involved. Volume changes due to mutual solubility of the phases should be noted for precise measurements. Both the extraction and sampling must take place at the same temperature, since the values of many properties change as a function of temperature.

When distribution ratios are small, and also in many production-scale systems, continuous extraction processes are used. Continuous extractions are by definition also dynamic, since the two phases are continuously passed through each other. High efficiency continuous extractions depend on the viscosity of the two phases, the equilibrium rates, distribution ratios, solvent volumes, and the surface/contact area between the phases.

Countercurrent Extraction

A continuous extraction approach (though sometimes performed in a batch-wise manner) is countercurrent extraction. In countercurrent extraction both phases are continuously added (or changed) and flow in opposite directions as the extraction progresses. (When only one phase is continuously added, the procedure becomes a crosscurrent extraction.) In the case of both countercurrent and crosscurrent extractions, the feed is repeatedly (continuously) contacted or washed with extracting solvent. The number of theoretical stages is maximized by using solvents with favourable distribution coefficients (see sub-

sequent discussion) or by increasing the solvent-to-feed ratio. Commonly, these processes employ up to eight theoretical stages. Although they have been replaced by chromatographic methods in many cases, countercurrent extractions are useful in that they use solvent only, without sorbents, and relatively mild conditions. They are favoured when the distribution coefficient is small. However, countercurrent extractions use large volumes of solvent and are not advantageous when large amounts of solute are to be isolated. The Craig countercurrent device, popularly used to study partition chromatography, is a discontinuous, differential migration process, since the extraction stages are performed step-wise rather than as continuous extractions.

Solvent Considerations

The requisite immiscibility and viscosity of the extracting fluid have been discussed.

Several other solvent properties that are important to the extraction process are listed here.

- Selectivity, i.e. the ability to extract the material of interest in preference to other, interfering material. Solvent selectivity can be supplemented through the use of adsorbents and secondary solvents, and by other means.
- High distribution coefficient to minimize the solvent-to-feed ratio.
- Solute solubility, which is usually related to polarity differences between the two phases, leading to low solubility in the raffinate.

- Ability to recover the extracted material. Thus the formation of emulsions and other deleterious events must be minimized.
- Capacity, the ability to load a high amount of solute per unit of solvent.
- Density, as density differentials are needed for countercurrent flow. The solvent density is related to solubility in supercritical fluid extracting solvents.
- Low interfacial tension to facilitate mass transfer across the phase boundary. Interfacial tension tends to decrease with increasing solute solubility and as solute concentration increases. In liquid-liquid extraction low interfacial tension allows the disruption of solvent droplets (entrained in the feed solution) with low agitation.
- Low relative toxicity.
- Nonreactive. In some instances, such as ion-exchange extractions, known reactivity in the extracting fluid is used. In addition to being nonreactive with the feed, the solvent should be nonreactive with the extraction system (e.g., non-corrosive) and should be stable.
- Inexpensive. Cost considerations should emphasize the energy costs of an extraction procedure, since, for a given extraction method, capital costs are relatively constant.

Solubility

Of the solvent properties necessary for extraction, solubility of the solute into the solvent is of fundamental importance. The general understanding of 'like dissolves like' is handy in the preliminary choice of extraction solvents. Solvent classification schemes are often helpful, especially if the selectivity of solvents is of interest. The Snyder selectivity triangle results in eight classifications of solvents according to proton donor, proton acceptor, and dipole interaction properties. Another solvent classification scheme is as follows.

- Class 1 solvents: capable of forming three-dimensional networks of strong hydrogen bonds.
- Class 2 solvents: have active hydrogen atoms and donor atoms, but do not form three-dimensional networks.
- Class 3 solvents: contain donor atoms, but not active hydrogen atoms.
- Class 4 solvents: contain active hydrogen atoms, but not donor atoms.
- Class 5 solvents: do not have hydrogen-bonding capability or donor atoms.

Comparisons of solubility values can give approximations for the partitioning of a solute between two

solvents. Although experimentally generated solubility data is preferred, relative solubility scales can be used for estimation purposes. However, it is important to remember that no scale has been developed that completely accounts for all of the intermolecular interactions influencing solubility.

The most common relative solubility scale is the Hildebrand solubility parameter scale. The Hildebrand solubility parameter, δ , is a measure of the cohesion (interaction) energy of the solvent-solute mixture and is defined by $\delta = (\Delta E_v/V)^{1/2}$, where E_v is the heat (energy) of vaporization necessary for volume V . Thus, the ratio $\Delta E_v/V$ is the cohesive energy density. The 'total' Hildebrand solubility parameter (δ_t) is related to the hydrogen-bonding ability (δ_h), the dispersion coefficient (δ_d), and the polarity (δ_p) by $\delta_t^2 = \delta_h^2 + \delta_d^2 + \delta_p^2$. Consequently, there is a strong correlation between the Hildebrand solubility parameter value and the polarity. For extraction purposes, it is preferable to use solvents that have δ values similar to those of the solutes of interest. Several references provide detailed development of the Hildebrand solubility parameter, and similar scales, and these values are tabulated for several solvents.

When supercritical fluids are used in place of liquids, modified versions of the Hildebrand solubility parameter are used in which $\delta = 1.25P_c^{1/2}(\rho/\rho_{liq})$ or $\delta = \delta_{liq}(\rho/\rho_{liq})$, where P_c is the critical pressure, ρ is the density, and δ_{liq} and ρ_{liq} are the Hildebrand value and density at liquid conditions. This modification for supercritical fluids, while only approximate, provides for reference to liquid values of polarity and other 'chemical' properties, and for the relationship between supercritical density and solubility.

Solvent Removal Methods

Once the solute is extracted into the extraction solvent, it generally must be isolated from the solvent. Thus, the chosen solvent should facilitate this procedure. Most simply, this is done by evaporation or distillation of the solvent from the solute. Distillation procedures can be quite efficient. Other solvent removal methods include precipitation, adsorption, and back-extraction. Precipitation of the solute and subsequent decanting or filtering usually results in low yields. Where appropriate, these yields can be moderately improved by converting the (ionic) solute to the salt. Adsorption onto a suitable stationary phase is especially desirable if additional solute purification is needed. Back-extraction also results in additional purification. This secondary extraction can use a third solvent or can be an extraction back into the original feed solvent (for liquid systems) through changes in the distribution ratio by adjusting parameters such as pH. For example, with ionizable

compounds and an aqueous phase the fraction ionized into the aqueous phase is approximated by the Henderson–Hasselbach equation (i.e., $\log \text{ionized} (\alpha) / \log \text{nonionized} (1 - \alpha) = \text{pH} - \text{p}K_a$). So in this example, the ionic form of 99% of the solute can be changed by adjusting the pH by two units from the $\text{p}K_a$.

Extraction of Ions

The extraction of ionic species, especially from aqueous phases into organic phases, often requires somewhat specialized treatment, generally ion-exchange or ion-pairing extraction. In ion-exchange extraction the ionic compound is covalently bonded to a compound of opposite charge, resulting in a neutral species. The more common ion-pairing extraction is based on formation of a neutral ion pair through the interaction of the ionic species of interest with a counterion. The resulting neutral ion pair is soluble in organic solvents. Usually solubility is greater in polar solvents. The solubility in the organic solvent is usually increased by selecting an ion-pair reagent containing a nonpolar portion in addition to the charged moiety. Counterions used are generally soft acids or bases possessing large ionic radii. In addition to selection of the counterion, experimental parameters that can influence ion-pair extractions include pH, ionic strength (i.e., the total concentration of all ionic species in the sample), organic solvent, and flow rate.

Solute Distribution

Chemical extractions proceed by a drive towards equilibrium. Consequently, knowledge of the equilibrium distribution of the solute between the phases is useful. Berthelot and Jungfleisch studied phase distribution in 1871 and twenty years later, in 1891, Nernst developed his distribution law in which $K_D = (\text{concentration of solute in phase 1}) / (\text{concentration of solute in phase 2})$, where K_D is the *distribution coefficient*. However, the simple ratio of solute concentrations is not thermodynamically rigorous, since it does not account for association or dissociation in either phase. The IUPAC (International Union of Pure and Applied Chemistry) definition of the *distribution ratio*, K' , includes all species of the same component and is used when the solute does not chemically react in either phase. This definition discusses the ratio, in organic–aqueous systems, as ‘the total analytical concentration of the substance in the organic phase to its total analytical concentration in the aqueous phase, usually measured at equilibrium’. This relationship follows from Gibbs’ phase rule in which: $P + V = C + 2$, where P is the number of phases, V is

the number of degrees of freedom (independent system variables), and C is the number of components. So for the example of a simple extraction with two immiscible phases and a single solute of interest, $P = 2$ and $C = 3$. At constant temperature and pressure, the number of degrees of freedom is one, meaning the solute concentration in each phase is fixed. (Note that while activities and concentrations are not strictly equivalent, they can generally be treated equally over practical concentration ranges.)

Distribution ratios cannot be determined from the relative solubility data for several reasons: (1) the extraction may not be at equilibrium, (2) mutual solubility of the phases, and (3) solubility differences, for example between hydrated and anhydrous forms of the solute. Therefore the ratio of solubilities is not the same as the distribution ratio for these same reasons. However, if solvation is properly considered, the relationship between solubility and extractability can be determined, especially for liquid–liquid systems. Assuming equilibrium and phase immiscibility, the fraction of solute extracted, E , can be determined for a given phase ratio, V or V_1/V_2 , by the expressions:

$$E = C_1 V_1 / (C_1 V_1 + C_2 V_2) = K_D V / (1 + K_D V)$$

$$E = 1 - [1 / (1 + K_D V)]^n$$

$$\%E = 100 K_D / (K_D + V_2 / V_1)$$

where C is the solute concentration, n is the number of extractions (assuming the extracted phases are pooled), and subscripts 1 and 2 represent the two phases. A practical application of the use of distribution ratios is shown in Figure 3, which illustrates the need for a series of extraction stages, rather than simply, an increase in the volume of extraction

Figure 3 Relationship between distribution ratio and amount (percent) of solute extracted for (A) phase ratio of one, (B) phase ratio of two, and (C) phase ratio of ten.

Table 2 Solute distribution between phases in multistage extraction

	Stage				Distribution of solute
	0	1	2	3	
Initial equilibrated sample	<i>a</i>				
	<i>b</i>				
First transfer	0	<i>a</i>			
	<i>b</i>	0			
Amount of solute in each stage	<i>a</i>	<i>b</i>			<i>a + b</i>
Second transfer	0	<i>ab</i>	<i>a</i> ²		
	<i>b</i> ²	<i>ba</i>	0		
Amount of solute in each stage	<i>b</i> ²	<i>2ab</i>	<i>a</i> ²		<i>(a + b)</i> ²
Third transfer	0	<i>ab</i> ²	<i>2ba</i> ²	<i>a</i> ³	
	<i>b</i> ³	<i>2b</i> ² <i>a</i>	<i>ba</i> ²	0	
Amount of solute in each stage	<i>b</i> ³	<i>3b</i> ² <i>a</i>	<i>3a</i> ² <i>b</i>	<i>a</i> ³	<i>(a + b)</i> ³
Amount of solute in each stage upon subsequent transfers					<i>(a + b)</i> ^{<i>n</i>}

solvent. In this example, assuming a constant distribution ratio of 1, a doubling of the extraction volume (from phase ratio = 1 to phase ratio = 2, where the phase ratio is the simple ratio of the extraction solvent volume to the sample volume) only increases the amount extracted in a single stage from about 50% to about 66%. A ten-fold increase in solvent volume only increases the amount extracted from about 50% to about 90%. As additional stages are added, the solute distributes itself in each phase. This is similar to the distribution studied by Craig and shown in Table 2. In this case, a solute distributes itself between the two phases in the ratio of a/b and the amount of solute in each stage can be determined. In practice, however, the stages are combined to maximize solute yield and recovery.

Diffusion

In addition to the roles of solubility and distribution ratios during the equilibrium portion of an extraction, diffusion is the largest factor influencing the extraction of solutes. Diffusion is that spontaneous, irreversible process by which a compound moves from an area of high concentration to an area of lower concentration, resulting in a concentration equilibrium within a single phase. More rigorously, the diffusional flow, J , of a compound is defined as the mass of the material of interest passing through a reference surface during a specified time, and laws of diffusion can correlate this diffusional flow with the concentration gradient responsible for the flow. If the rate of mass flow per unit area, or the

diffusion flow, J , is in $\text{g cm}^{-2} \text{s}^{-1}$ and concentration is in mol cm^{-3} , Fick's first law of diffusion provides a correlation with the concentration gradient such that $J = -D(\Delta c/\Delta x)$, where D is the diffusion coefficient (given in $\text{cm}^2 \text{s}^{-1}$) and $\Delta c/\Delta x$ is the concentration gradient (in g cm^{-4} , concentration c is in g cm^{-3} and area x is in cm^2). Thus, Fick's first law defines a diffusion coefficient that is independent of solute concentration and is unique to every solute-solvent pair at constant temperature. Generally, this diffusion coefficient, D , is in the range 10^{-5} – $10^{-6} \text{cm}^2 \text{s}^{-1}$ in liquid solutions, whether aqueous or organic. When a steady state cannot be assumed, the concentration change with time must be considered, leading to Fick's second law of diffusion, $\Delta c/\Delta t = D(\Delta^2 c/\Delta x^2) = DV_{\text{mol}}^2 c$, where t is time (s) and V_{mol} is molar volume. Thus in non-steady-state conditions the temporal rate of concentration change is proportional to the spatial rate of concentration change in the direction of the concentration gradient.

Diffusion in Liquids

In liquid systems, with small or medium-sized molecules in dilute solution, diffusion is highly dependent on viscosity, η , and consequently on temperature, T . Assuming a spherical particle, diffusion in liquids can be expressed by the Stokes-Einstein equation, $D = (10^{-7} T/\eta V_{\text{mol}}^{1/3})$.

Figure 4 Schematic diagram of the role of interfacial diffusion in liquid-liquid extraction. Each stagnant layer is about 10^{-2} – 10^{-4}cm . In this depiction, the molecules diffusing through the liquid-liquid interface contain a moiety (\times) with an affinity toward phase 2 and a moiety ($-$) with an affinity toward phase 1.

For the purposes of extraction, the rate of diffusion across the liquid–liquid boundary layer is of primary importance. This diffusion rate is dependent on solute shape and size and on solvent viscosity. Agitation or turbulence at the liquid–liquid interface can enhance the rate of diffusion across the phase boundary, but there is a practical limit to the degree of agitation in an extraction mixture. **Figure 4** depicts the liquid–liquid system, including the stagnant films on either side of the phase boundary. In practical extraction examples the bulk phases are adequately stirred so that diffusion in the bulk phases can be neglected. However, the interfacial stagnant layers are about 10^{-2} – 10^{-4} cm (compared with diffusion coefficients in the range 10^{-5} – 10^{-6} cm² s⁻¹) and must be considered as controlling the overall extraction kinetics. Moderate shaking or agitation can reduce the thickness of the stagnant, or stationary, films. If agitation is too vigorous, solutes in the mixture are given a high translational motion without an increase in the rate of solute movement to the phase interface. As phase dispersion increases, the relative velocity of the two phases decreases, until the limiting case of an emulsion (in which relative velocity becomes zero) is reached.

Diffusion in Solids

When extracting solutes from solid samples, one must not only overcome the solute–sample attraction, but

the solute must diffuse with the solvent back out of the porous solid sample. This diffusion through the pores of a solid sample is influenced by the geometry or tortuosity of the pore structure (e.g. the diffusion path length). Diffusion in solids, assuming weak solute–sample sorption (i.e., a linear isotherm), is expressed by $D_{\text{eff}} = (\phi D)/\gamma(K_D + 1)$, where D_{eff} is the effective (or apparent) diffusivity, ϕ is the fraction of space available to the extracting solvent, K_D is the distribution coefficient (expressed as the ratio of solute concentration in the solid volume to solute concentration in the solvent volume), D is the (true) diffusivity in the bulk solvent, and γ is a tortuosity factor. With ionic solutes, if the pore wall carries an electric charge, diffusion is also affected by the electrical potential gradient.

This knowledge of diffusion through porous solids can provide an understanding of practical extractions. **Figure 5** represents an overview of the processes occurring when extracting solutes from solids. This understanding is described in the ‘hot-ball model’ advocated by Professors Keith Bartle and Tony Clifford at Leeds University. For example, with small quantities of extractable compounds that diffuse out of the homogeneous spherical particle into the extraction solvent, the extracted compounds are infinitely dilute. The extraction rate is obtained through the expression for the ratio of the mass, m , of

Figure 5 Schematic diagram of major physical/chemical processes that may occur during the extraction of solutes from a solid sample particle.

extractable material remaining after time t to the initial mass of extractable material, m_0 , where $m/m_0 = (6/\pi^2)\Sigma(1/n^2)\exp(-n^2\pi^2Dt/r^2)$, where n is an integer, D is the diffusion coefficient of the material in the sample matrix, and r is the radius of the spherical sample. This equation reduces to a sum of exponential decays, and a plot of $\ln(m/m_0)$ versus time eventually becomes linear. The physical explanation for the model is that, during the initial phases of an extraction, there is a concentration gradient at the surface of the sphere and diffusion from the sphere is rapid. This corresponds to the 'equilibrium' region (see Figure 1). When the concentration across the entire sphere becomes even and the rate of diffusion (and, hence, extraction) is a simple exponential decay, the 'diffusion' region of the extraction process (shown in Figure 1) is reached. Extrapolation of this linear portion of the plot of $\ln(m/m_0)$ versus time can be used to determine the time (or amount of solvent) necessary to achieve quantitative extraction recoveries.

Extraction Techniques

The previous sections described, in a practical way, the theory and the physical chemical basis for extraction. The importance of the phase interface was noted, and it was emphasized that mass transfer is a function of several properties, such as diffusion, viscosity, density, interfacial tension, turbulence, etc. Extractions are more practically a function of those experimental parameters that affect diffusion, viscosity, etc. For example, temperature plays one of the largest roles in improving extraction yields (though selectivity may suffer), as does the particle size of solid samples. The geometry of the extraction system must also be considered.

Chemical extractions can take on a number of embodiments. This section will provide a brief overview of these (mostly analytical) extraction techniques. The most important, and/or newly developed, are discussed in detail in other articles. While the methods discussed here are categorized as 'liquid' or 'solid' methods, there is some degree of exchange and methods used predominantly for solids can also be adopted for liquids in many cases, for example.

Extraction from Liquids

Liquid-liquid extraction (LLE) During LLE the solute partitions between two immiscible liquid phases. The devices shown in Figure 2, as well as the common separatory funnel, are simple laboratory methods for performing LLEs. The extraction solvents are chosen based on solubility differences

with the sample solvent. For example, with neutral, acidic, or basic aqueous samples, organic solvents such as hydrocarbons, ethers, halocarbons, and aliphatic alcohols or ketones are commonly used. LLE can be performed in batch or continuous mode, can accommodate unattended operation, is suitable for systems with low distribution ratios, and uses relatively low solvent volumes. If solvent reflux is used care must be taken to avoid loss of volatile solutes and thermal degradation of the sample or the solute. In all LLEs the formation of emulsions should be avoided.

Solid-phase extraction (SPE) In SPE, a solid, or a liquid phase adhered onto a solid support, is used to selectively (and reversibly) retain sample components as the sample solution passes through the extraction device, usually configured as a packed bed or disk. The solute is then removed from ('washed off') the sorbent phase with the extracting solvent. In essence, this extraction procedure can be thought of as a crude chromatographic method and many of the same principles, and stationary phases, apply. SPE is especially useful for improving the selectivity of an extraction for instance to 'clean up' dirty samples for analysis. The selective stationary phases can retain solutes based on ionic or hydrogen bonding, or dipole-dipole, dipole-induced dipole, or dispersion forces. The primary advantages of the technique, in addition to selectivity, include speed, efficiency, reproducibility, economics, and safety.

Another, specialized, version of SPE is solid-phase microextraction (SPME). With SPME, the sorbent phase is coated on a small fibre which then comes in contact with the sample. The extracted solutes are eluted from the fibre, in most cases directly by the chromatographic inlet system. The advantage of this technique is that the extraction is coupled directly with the analytical chromatography (so that all of the solute is introduced into the chromatographic system) so that the system can be 'solvent-free'.

Extraction from Solids

It is estimated that 40% of all analytical samples are solids. This significant portion of the analytical sample load represents the most difficult extraction challenge, since solute interactions with the sample matrix must be overcome and the solute must then diffuse through the solid sample. As a result, the development of extraction methods for solids has focused on improving the diffusion issues.

Leaching Leaching simply involves soaking the sample in the extraction solvent for a prescribed period, and is a batch process. Because of the adsorp-

tive properties of the sample and the slow diffusion through a solid, leaching is not a very efficient extraction method. Improvements to simple leaching can be made by placing the extraction vessel on a heat source (such as a heating plate or steam bath). Agitation, as in shake-filter methods, and a decrease in the sample particle size can also improve recoveries. An adaptation of leaching is forced-flow leaching. In this case the sample is placed in a tube and solvent flow is forced (under pressure) through the tube. In many instances the solvent is heated to near its boiling point and forced-flow leaching can be a continuous process.

Soxhlet extraction This common procedure, which uses the device shown in Figure 2A, was developed nearly 100 years ago and is still in routine use. The sample is placed into a porous container (called a thimble) and the volatile extraction solvent is continuously refluxed and condensed through the sample. Although the method can be slow (12–24 h Soxhlet methods are not uncommon), the apparatus can be left unattended with multiple extractions being performed by a bank of Soxhlet extractors. As with any technique using applied heat, loss of volatile compounds and thermal degradation are concerns. Because of its routine use in established analytical procedures, Soxhlet extraction is undoubtedly the extraction method to which other methods for extracting solids are compared.

New developments in Soxhlet extraction include a high pressure system, developed by J & W Scientific, which allows liquid carbon dioxide to be used as the extraction solvent, and an automated version. The automated Soxhlet extractor allows the thimble to be immersed in the boiling extraction solvent for a prescribed period, before the extraction is completed in the more traditional Soxhlet approach. This two-step process can be 4–10 times faster than conventional Soxhlet extractions and use about half of the solvent volume.

Sonication Sonication or ultrasound extractions can be considered a development of leaching, in which ultrasonic energy is applied to disrupt solute-sample interactions and facilitate solute diffusion. The use of ultrasonic probes can be quite efficient.

Accelerated solvent extraction (ASE) (also called pressurized fluid extraction) This technique, developed by the Dionex Corporation, is commonly discussed using the trademarked name, accelerated solvent extraction. However, the more generic term pressurized fluid extraction is becoming more widely used. In this technique the sample is placed into a sealed container and solvent is pumped through this extraction vessel. Because a modest pressure is

applied, temperatures much greater than the atmospheric boiling point can be used with liquid extraction solvents. The technique is automated. This application of temperature greatly enhances solute solubility, diffusion, and viscosity, resulting in extractions that are qualitatively and quantitatively equivalent to Soxhlet in minutes instead of hours, and with significantly less solvent.

Microwave-assisted extractions In some respects microwave extractions can be thought of as a form of leaching with the addition of microwave irradiation. The microwave irradiation, when absorbed by materials with a permanent dipole, leads to heating. In a closed system, the approach is like ASE in the respect that temperatures greater than the atmospheric boiling point of the solvent can be achieved. This form of the technique is generally used with polar solvents (which absorb microwave energy). Open-cell approaches are generally used with non-absorbing solvents and samples with a high water content (or that otherwise possess a high dielectric constant). In this case localized heating in the sample allows extraction efficiencies to be improved.

Supercritical fluid extraction (SFE) SFE employs solvents, generally carbon dioxide (neat or with added co-solvents), at temperatures and pressures near or above the critical point. These high-temperature, high-pressure solvents have gas-like diffusion, liquid-like solvation properties, and do not possess surface tension. Hence, SFE can be quite rapid. With the use of carbon dioxide, the deleterious effects (e.g. cost, health and environment concerns, etc.) of organic solvents can be minimized. Another advantage of SFE is that solvating properties can be modified as a function of temperature and pressure, adding a selectivity advantage to the technique. In SFE the sample is placed in an extraction vessel and the supercritical fluid passes through the vessel in a series of static and dynamic steps. Upon depressurization of the extracting fluid the extracted solute remains in a solute collection region.

Gas-phase methods When volatile compounds are being extracted they can often be forced from the solid into the gas phase and subsequently trapped. In static methods the volatile compounds above the sample (often after heating) are simply trapped. Dynamic methods are exemplified by the purge-and-trap technique. In purge-and-trap, a continuous purge of the sample with an inert gas takes place and the volatile solutes are trapped onto a solid support. Thermal desorption is similar to the purge-and-trap technique, except the sample is heated ballistically to

higher, controlled temperatures to force the solutes into the gas phase. Each of these gas-phase methods have been modified for use with the SPME approach to solute trapping.

Future Directions

Chemical extractions are thought to be a mature science. However, progress is still being made. The key influences driving these advances include the need for faster and more selective extractions and extractions that use smaller (if any) amounts of organic solvents. Better predictive models to aid the design and scale-up of extraction processes will also continue to be of great interest.

Introduction

Overview of the Essential Elements of Separations Based on Froth Flotation

The objective of a flotation separation operation is to remove small hydrophobic particles from an aqueous suspension (pulp) by causing them to collide with, and to attach to, air bubbles. The bubble-particle aggregates rise through the suspension forming a froth at the upper surface of the pulp. The froth, which consists of the bubble-particle aggregates with inter-bubble water containing both hydrophobic and hydrophilic particles, forms a second phase where further enhancement of the hydrophobic/hydrophilic particle separation occurs, by water draining back to the pulp. The final product in which the hydrophobic particles are concentrated is removed as a froth overflow.

The science of the separation is primarily concerned with improving the selectivity of the hydrophobic particle attachment in the pulp through the addition of surface active chemicals. In addition, the hydrodynamics of the bubble-particle collision in the aerated suspension is important, as is the regulation

of the drainage of water-containing hydrophilic particles from the froth by controlling its structure, also with surfactants.

It is probably fair to say that the industrial practice of flotation is effective even in the absence of a complete understanding of its scientific basis. The successful application of flotation separations in industry can be classified into three areas.

Mineral Processing

Froth flotation is a widely used technique in the mineral processing industry as an early step in the process of concentrating a valuable material from an ore. It is preceded by crushing and grinding and may be followed by leaching/(ion exchange) electrowinning or smelting. In data cited by Merrill and Pennington from a US Bureau of Mines survey for 1960 nearly 200 million tons of raw material were processed annually by flotation in the USA from which 20 million tons of concentrates were recovered. These consisted of 34 different commodities which, although principally metallic and non-metallic ores and coal, also currently reflects an increasing interest in recycling waste material.

More recent data supplied by Bowes, courtesy of the Anglo-American Research Laboratories in Crown Mines South Africa, is given in **Table 1**. These figures are estimates and should be used with caution, as the

Table 1 World-wide flotation tonnages (millions of tons), 1991–7

	1991	1992	1993	1994	1995	1996	1997
Copper	950	960	960	960	1000	1000	1080
Lead	93.3	91.4	79.2	78.4	78.4	84.3	87.5
Zinc	119.8	121.5	111.9	110.6	114.2	118.9	119.8
Nickel and cobalt	19.6	19.4	18.9	19.9	23.9	25.6	27.2
Iron	125	126	124	123	129	136	139
Phosphate	378	382	374	371	389	412	420
Industrial minerals	52	52	51	51	53	56	57
Coal	54	54	53	53	55	59	60
Totals	1791.7	1808.3	1772.0	1766.9	1842.5	1951.8	1990.5

Calculated based on the tonnages of pure metal produced; the mine production of ores are based on the following data:

Copper: average grade 0.8% Cu mined, at a processing recovery of 90%

Lead: average grade 3.0% Pb mined, at a processing recovery of 95%

Zinc: average grade 5.7% Zn mined, at a processing recovery of 82%

Nickel: average grade 1.6% Ni mined, at a processing recovery of 85%.

Source: Bowes (1997) Personal communication, Anglo-American Research Laboratories, Crown Mines, South Africa.

processing recovery refers to the flotation operation only. Where other recovery techniques are used such as leaching of nickel laterites and the recovery by leaching and solvent extraction of by-product cobalt from copper mining, these figures have not been included. Lead and zinc are often mined together and the separate tonnages reported for flotation processing may be overstated. The figures given for iron, phosphate, industrial minerals and coal are based on the percentages of the total tonnages. It is felt that particularly for iron and phosphate the figures may be excessive.

Overall the total ores processed annually using froth flotation given in Table 1 are consistent with the figure of 2 billion tons given by Fuerstenau in 1996. It is expected that significant growth will be seen in the next decade with flotation processing of copper ores rising to 1.6 billion tons per annum which represents 55% of the total tonnage anticipated.

Froth flotation has proved itself to be an important process in the mineral industry and will only become more important in the future.

Non-mineral Processing Recycling

This includes deinking wastepaper, separating individual components from plastic wastes, and effluent treatment of textile and smelter wastes.

Wastepaper deinking The growth of production has increased rapidly in recent years from 5.9 million tons per year in 1981 to 17.6 million tons per year in 1991. It is estimated that by 2001 the production of deinked waste will have increased to 31 million tons/year.

The objective of wastepaper deinking is to rid the grey repulped waste stock of unwanted particulates, usually inks. The reflectance of sheets of paper produced from the retreated waste pulp to light at 457 nm gives a measure of the brightness. However, changes in brightness are themselves not necessarily a complete description of the effectiveness of the separation of ink, as brightness changes are also associated with the presence of white inorganic fillers.

Prior to flotation the wastepaper is repulped in water at about a 15% suspension of fibre in water, in the presence of either a sodium soap or an anionic surfactant such as sodium dodecyl sulfate (SDS). These provide detergency, liberating the ink particles from their associated fibres. In some deinking plants this pulp is diluted to about a 1% fibre suspension, before being fed to a flotation separator in which the grey pulp suspension is aerated using cell designs similar to those in the mineral industry. The product stream from these cells is an inky foam, which is the reject, and a non-floated fibre suspension below the froth level which is the deinked product.

Although this process has some resemblance to minerals flotation there are significant differences. Specifically these relate to the properties of the fibre suspension. Their settling rate is low in any event, but as flocculated agglomerates they can trap small bubbles which give them a buoyancy that makes them easily entrainable in the water associated with the air bubbles forming the foam. This can result in the reject stream being as much as 10% of the feed, although the ink and its associated print vehicle oil will only account for between 1 and 2% of the feed fibre. Of this 1–2% only 10–20% is cellulose the rest being the oil/vehicle required for printing.

The mass of the reject stream is a serious environmental problem with land-fill costs rising sharply. There is also little information relating to the brightness increase of the deinked pulp as the removal of talc filler with the reject stream will seriously reduce the brightness of the final paper. It is clear that while deinking by flotation is potentially a valuable technique much fundamental work needs to be done before it reaches an acceptable level of separation.

Separation of plastic components from solid waste It has been said that of the 16.2 million tons of plastic waste generated annually in the USA only 2.4% is recycled with the rest being discarded to land-fill. As

mentioned earlier, this is becoming an increasingly expensive option and a scheme is envisaged where the individual components, polyethylene terephthalate (PET), polyethylene (PE), polyvinyl chloride (PVC) and polypropylene (PP), can be separated and hence become reusable.

PVC and PET can be separated from the others by gravity separation and by using 190 ppm of a surfactant, methyl iso-butyl carbinol (MIBC), at pH 11 in a 1% suspension of the solids, the PVC can be removed in a flotation froth giving high recoveries and purities, leaving pure PET in the unfloated tailings. This process, although at an early stage, offers a promising recycling opportunity.

Recovery of metals from refinery effluents It is possible that these may also respond to the use of froth flotation in transforming environmentally hazardous discharges into economically attractive sources of raw materials.

It is clear that considerable development work will be required in all the new applications and while it is sensible to make use of the extensive knowledge of the minerals industry of this separation technique, solving the special problems associated with each new application will most profitably be done by application of scientific fundamentals.

Water and Waste Treatment

Removal of contaminants from domestic water The technique of dissolved air flotation (DAF) is used as an alternative to sedimentation after flocculation in the preparation of water for domestic consumption. The bubbles are generated by first saturating a fraction of the treated raw water with air under pressure and then depressurizing in the total water. After depressurization the bubbles rise through the bulk solution, where they will be entrapped by the flocculated impurities. The bubble-floc aggregates rise to an overflow where they are removed. DAF differs from mineral flotation in that the bubbles are very small and are not stabilized by added surfactants, and there is no selective attachment. The justification for its use is that the aerated flocs rise faster than the settling rate of ordinary flocs whose density is close to that of water and whose structure favours a high resistance to settling flow.

Separation of dispersed oil from production water The processing of oil from offshore wells involves the removal of suspended solids from the oil and the separation of an oil-water mixture. Both the solid particles and the dispersed oil droplets are very fine; in the region of 10–50 μm . The processing involves

the concentration of oil from a 5–50% by volume in water to 95–100% oil. This may involve a multistage operation particularly for very wet crudes, with a second concentrator stage treating the oil-rich product from the first stage to achieve the desired final oil purity.

If there is a second stage its water-rich waste stream is recycled to the first stage feed. The waste product from the first stage is water containing up to 0.1% oil by volume dispersed as ultrafine droplets. Before this water can be discharged, its oil content has to be reduced to comply with strict environmental standards both with respect to its oil content and the biological oxygen demand (BOD). Froth flotation has been used particularly in final clean-up units because of the small droplet size. DAF has been used as the bubbles coming out of solution following a reduction in pressure are thought to nucleate directly on the droplets. Unfortunately, the rise velocity of these air-droplet aggregates is so slow that extremely large cells are required. Their operation is in turn adversely affected by the pitching motions of floating rigs. Induced gas flotation (IGF) has also been used when the air is added to the feed stream at the throat of a Venturi nozzle. These have higher recovery rates but lower oil removal efficiencies than the DAF units. These reasons, together with the perceived high chemical costs, have favoured the use of liquid-liquid hydrocyclones in these situations.

Quantitative Measure of Flotation Performance

The performance of any separation unit is usually defined in terms of the fractional recovery (removal) R of the valuable product (contaminant) and its purity (concentration) in the product (waste) stream G .

Grade-Recovery Curves for Mineral Beneficiation

To characterize the flotation step in the beneficiation of a mineral ore, it is necessary to postulate that the mixture consists of at least two distinct particle populations, one largely valuable and the other principally waste (gangue). The gangue will invariably consist of several different mineral types, the presence of each being undesirable in the valuable mineral. Each population is characterized by a size distribution, and the amount of undesired material it contains. The fraction of misplaced material in a particular population can almost invariably be reduced by a sequence of size reducing steps usually consisting of primary and secondary crushing followed by fine grinding.

Increasing the fineness of grinding is said to liberate the valuable species from its associated waste

component. This will result in increasing the fraction of the desired component in the valuable mineral recovered and reducing its amount in the gangue. While liberation of the valuable component is clearly desirable, overgrinding will increase the power consumption of the mills, and as observed by Klimpel, also possibly introducing difficulties into the flotation process and subsequent downstream processing.

It is important to have a measure of the effectiveness of separation before an optimal solution can be identified. From a systems viewpoint, the flotation operation in mineral processing will separate a feed stream, F , into two product streams, a concentrate stream, C , containing an increased fraction of the valuable component and a tailings stream, T , containing a reduced amount of the valuable component. The following overall mass balance will apply:

$$Fx_F = Cx_C + Tx_T \quad [1]$$

where x_F , x_C and x_T are the mass fractions of the valuable component in the feed, concentrate and tailings, respectively. The performance measurement is characterized by two parameters. The fractional recovery R of the valuable component in the concentrate:

$$R = \frac{Cx_C}{Fx_F} \quad [2]$$

and its purity (grade) in the concentrate stream. The grade may simply be the mass fraction x_C or can be normalized between 0 and 1:

$$G = 1 - \frac{1 - x_C}{1 - x_F} \quad [3]$$

The upper limit, $G = 1$, clearly follows from the concentrate mass fraction of valuables, $x_C = 1$, while the lower limit, $G = 0$, presumes that the worst system performance is associated with no upgrading of the valuable mass fraction in the concentrate with respect to its concentration in the feed, although negative grades are mathematically possible.

Attainable Regions

The grade–recovery curve divides the grade–recovery space, $0 \leq G, R \leq 1.0$, into attainable and non-attainable regions. The grade–recovery curve is a function of a set of operational controls of which the fineness of grind of the feed is one. The others are actions that affect the selective attachment of the valuable component to air bubbles and the preferential drainage of the waste material back from the

froth. The optimal performance of the flotation operation is defined in terms of the minimum cost of achieving a particular grade–recovery target.

Pulp Microprocesses

Wetting of the Particles' Surfaces

The particles are always dispersed in water and the nature of the wetting of their surfaces is critical for the effectiveness of the flotation separation.

Figure 1 shows the concept of an attached water film in which water dipoles are held by van der Waals forces together with ions held by electrostatic interaction with charges on the particle surfaces.

The stability of the adsorbed water film on the solid surfaces is clearly fundamental to the selective attachment of bubbles. Qualitatively for hydrophilic particles the water film is strongly bound to the solid, and hence is stable; conversely for hydrophobic solids the water film is weakly bound and will fail more readily.

The attachment of hydrophobic particles to bubbles is usually considered to consist of two sequential stages. First, the particle must collide with (intercept) the bubble. The second stage after interception has two components: (a) a bubble–particle contact time and (b) an induction time which is that required for the water film between the particle and bubble to thin to a point of failure at which point attachment is presumed to occur.

The selectivity of the separation is commonly enhanced by the adsorption of surface active chemicals onto the surfaces of the solid particles. These reagents have a molecular structure which has a polar and

Figure 1 Model of a metal electrolyte interface showing film of water dipoles. Reproduced with permission from Leja J (1982) *Surface Chemistry of Froth Flotation*. New York: Plenum Press.

a non-polar end. Ideally, they will strongly attach to the valuable particles through their polar ends, with their non-polar ends confer an increased hydrophobicity. For the waste particles no attachment is considered to take place and consequently no hydrophobic increase will occur.

Clearly the choice of a suitable reagent is critical and is highly specific to a particular separation. Although the choice of reagent(s) for a particular separation usually has evolved with experience, the search for ever more effective reagent mixtures is an area of continuing research and development. A sound basis for these investigations is to develop an understanding of the free energy changes at the solid–water and bubble–water interfaces, consequent on changes of the reagent types and conditioning procedures.

Particle Surface Hydrophobicity

Theoretical basis for estimation To describe bubble–particle attachment after interception mathematically it is necessary briefly to review the nature and magnitude of the forces acting across the various interfaces.

After the initial interception, the particle and bubble will be separated by a water film. The film will become thin because of the forces of attraction between particle and bubble. The rate of thinning is determined by the dissipation of the kinetic energy of the particle on impact, associated with a resultant of long-range London–van der Waals molecular attraction (dispersion forces), capillary forces generated by the distortion of the bubble surface during the impact, electrostatic interactions between the uncompensated surface charges on the solid and those in the adjacent water layer, and as has been shown by Xu and Yoon, an additional force of attraction which appears to exist between two hydrophobic surfaces.

If the film thins to a critical value, failure will occur that will result in a successful attachment event. Both the thinning process and the critical thickness of the film must clearly depend on the interaction energy of the particle–water interface.

For the van der Waals forces of attraction, a treatment of the dispersion energy between a single gaseous atom and a slab of infinite extent is outlined by Adamson as:

$$\varepsilon(h_x)|_{\text{atom-slab}} = -\frac{\pi}{6}nC_1 \frac{1}{h_x^3} \quad [4]$$

where $C_1 = \frac{3}{4}h\nu_0\alpha^2$ and $\varepsilon(h_x)|_{\text{atom-slab}}$ is the potential energy of interaction in ergs/molecule at a separation distance h_x (cm), N_0 is the Avogadro number (6.02×10^{23} molecules/g mol wt) for water from

Adamson, $h\nu_0 = 18 \text{ eV} (= 18 \times 10^{-12} \text{ ergs})$, α (polarizability) $= 1.46 \times 10^{-24} \text{ cm}^3$. Since ρ_w density of liquid water g cm^{-3} and $n = N_0\rho_w/18 = 3.34 \times 10^{22}$ molecules/cm³ using these figures $C_1 = 28.8 \times 10^{-60}$ ergs cm⁶.

The dispersion energy between two infinite flat surfaces after integration is:

$$\varepsilon(h_x)|_{\text{slab-slab}} = -\left(\frac{\pi}{12}\right)\frac{(n^2C_1)}{h_x^2} \quad [5]$$

where $\varepsilon(h_x)|_{\text{slab-slab}}$ is in ergs cm⁻².

Fowkes has equated $\varepsilon(h_x)$ of eqn [5] to γ_s^d , the dispersion component of the total energy for water. As will be shown later, he has linked this dispersion energy with the physical adhesion energy at the interface between two different phases.

The dispersion energy for liquid water, γ_w^d , is calculated from eqn [5] to be $35.8 \text{ ergs cm}^{-2}$ using the values given above and a value of 2.76 \AA for the average intermolecular distance. This is somewhat higher than the experimentally determined value of $21.8 \text{ ergs cm}^{-2}$ from contact angle measurements, but nevertheless it is valuable as it gives a theoretical basis for the forces of attraction at the interface between two immiscible phase surfaces. This is relevant to studies where the adsorption of a surfactant (collector) on a solid surface is used to modify the surface's hydrophobicity.

Eqn [5] is usually written in terms of, A , the Hamaker constant, which is specific for a given separation; for water $A = \pi^2 n^2 C_1 = 0.3 \times 10^{-12}$, and on average is of the order of 10^{-12} ergs:

$$\varepsilon(h_x)|_{\text{slab-slab}} = -\left(\frac{1}{12\pi}\right)\frac{A}{h_x^2} \quad [6]$$

The attraction stress between the two surfaces is:

$$\frac{\partial \varepsilon(h_x)|_{\text{slab-slab}}}{\partial h_x} = \frac{A}{6\pi h_x^3} \text{ (dynes cm}^{-2}\text{)}$$

For a condensed system involving different phases the potential energy of interaction is still given by eqn [6] but with a modified Hamaker constant.

Consider a particle, 1, and an adjacent bubble, 2, in a water medium, 3. The particle and the bubble surfaces will be associated with water molecules. In the simplest case the film on the particle will consist of OH⁻ ions as well as molecular water dipoles and will be of the order of a monolayer in thickness,

which is the effective range of the van der Waals attractive forces. The bubble will have a layer of surfactant on its surface which will be orientated with its polar end in the water and the hydrophobic end in the air.

The interaction energy is expressed in terms of a net Hamaker constant, A_{132} , which is approximated by Adamson as a simple linear relationship:

$$A_{132} = A_{12} - (A_{13} + A_{23} - A_{33}) \quad [7]$$

The binary Hamaker constants expressed above refer to two-surface interactions only. Some of these are physically difficult to interpret, but are nevertheless useful in formulating a conceptual understanding. With these reservations, A_{12} is the interfacial energy between a solid particle and a bubble separated by a vacuum and A_{33} is the interaction energy between water molecules.

A_{13} and A_{23} are the Hamaker constants representing the particle–water and bubble–water interaction energies. If these energies are low with respect to the mutual interaction energy of the water molecules then A_{132} will be greater than the interaction A_{12} . The enhanced attraction between the particle and the air bubble in the presence of water reflects *hydrophobic bonding*.

Leja quotes interaction energy potentials and London dispersion forces for various configurations following integration of atom–atom interaction energies. The dispersion force of attraction between two spheres of radius R_1 and R_2 , for example, is given by:

$$\text{at } h_x \ll R_1, R_2, \quad F = \frac{AR_1R_2}{6b_x^2(R_1 + R_2)} \quad [8]$$

Experimental characterization of hydrophobicity – contact angle Interfacial energies for liquids may be measured by surface tension, while those for solid–liquid interfaces may be inferred from contact angle measurements.

If a liquid is placed on a solid surface it will form a droplet (Figure 2). The droplet will have a definite angle of contact, θ , with the surface. The change in the free energy ΔG^0 of the three-phase contact surface if the area of contact, ΔA_s , between the droplet and the surface were to change slightly is:

$$\Delta G^0 = \Delta A_s[(\gamma_{SL} - \gamma_{SV}^0) + \gamma_{LV} \cos(\theta - \Delta\theta)] \quad [9]$$

where γ_{SL} , γ_{LV} and γ_{SV}^0 are the interfacial energies for solid–liquid, liquid–vapour and solid–saturated vapour. At equilibrium this leads to the Young

Figure 2 Contact angle θ of liquid droplet on a solid surface.

equation:

$$\lim_{\Delta A_s} \frac{\Delta G^0}{\Delta A_s} = 0, \quad \gamma_{SL} - \gamma_{SV}^0 + \gamma_{LV} \cos \theta = 0 \quad [10]$$

Bangham and Razouk observed that as γ_{SV}^0 represented the energy of a surface in contact with a saturated vapour of partial pressure p^0 , there must be present on the surface a film of condensed vapour with its own surface energy π^0 . The total surface energy of the solid is thus:

$$\gamma_S = \gamma_{SV}^0 + \pi^0 \quad [11]$$

Substituting for γ_{SV}^0 in eqn [10] gives:

$$\gamma_{LV} \cos \theta = \gamma_S - \gamma_{SL} - \pi^0 \quad [12]$$

The interfacial energy of the solid–liquid interface γ_{SL} , can also be expressed as the sum of the surface energies of the individual phases separately, where γ_S is the surface energy of the solid, and γ_{LV} is the surface energy of the liquid in contact with vapour, and w_{SLV} is the work of adhesion which has to be subtracted:

$$\gamma_{SL} = \gamma_S + \gamma_{LV} - w_{SLV} \quad [13]$$

The work of adhesion for the three-phase contact is then obtained from the Young equation after substituting for γ_{SL} from eqn [12] into eqn [13]:

$$w_{SLV} = \gamma_{LV}(1 + \cos \theta) + \pi^0 \quad [14]$$

Equation [14] is a form of the Dupré equation that relates an increasing contact angle to a reduction in the adhesion energy between the solid surface and water, or alternatively to an increase in the hydrophobicity of the solid surface.

Fowkes modified the Girifalco–Good equation for the work of adhesion and suggested that it was due to the London–van der Waals dispersive forces in each phase rather than the total intermolecular energies. Equation [15] describes the resulting expression for the interface energy between a solid

and liquid:

$$\gamma_{SL} = \gamma_S + \gamma_{LV} - 2\Phi\sqrt{(\gamma_S^d\gamma_L^d)} \quad [15]$$

(Φ is commonly taken as unity).

Fowkes applied eqn [15] to eqn [12], to express a relationship between the contact angle and the dispersive energy of the solid surface, γ_S^d , this being considered to be a parameter most characteristic of the influence of the nature of the surface on the interface phenomena important in flotation:

$$\begin{aligned} \gamma_{LV} \cos \theta &= -\gamma_{LV} + 2\sqrt{(\gamma_S^d\gamma_L^d)} - \pi^0 \\ \cos \theta &= -1 + 2\sqrt{\gamma_S^d} \left[\frac{\sqrt{\gamma_L^d}}{\gamma_{LV}} \right] - \frac{\pi^0}{\gamma_{LV}} \end{aligned} \quad [16]$$

The dispersion forces in a particular solid, γ_S^d , can therefore be estimated by using contact angle measurements with different liquids obviously of known surface dispersion γ_L^d . Linear plots of $\cos \theta$ against the ratio of dispersive energies of the liquids confirm the validity of eqn [16] and the slope of the line gives $\sqrt{\gamma_S^d}$.

Experimental characterization of interfacial energies – adsorption studies Adsorption data may be used to estimate π which reflects changes in interfacial energies. These require knowledge of the adsorption isotherm, relating Γ , the mols of vapour adsorbed per square centimetre of solid surface with p , the partial pressure of the solute in the gas.

Bangham and Razouk derived an expression for π by integrating the Gibbs equation. This states that:

$$d\gamma = -\Gamma RT d \ln p$$

from which:

$$\begin{aligned} \pi &= - \int d\gamma = RT \int \Gamma d \ln p \\ \pi &= \gamma_S - \gamma_{SV} = RT \int_0^p \Gamma d \ln p \\ \pi^0 &= \gamma_S - \gamma_{SV}^0 = RT \int_0^{p^0} \Gamma d \ln p \end{aligned} \quad [17]$$

Harkins by defining γ_{SV} as being equal to $\gamma_{SL} + \gamma_{LV}$ related the energy π of the adsorbed liquid film to the

surface activities:

$$\pi = \gamma_S - (\gamma_{LV} + \gamma_{SL}) \quad [18]$$

By substituting for γ_{SL} from eqn [15], Fowkes obtained an expression which links γ_S^d with π as determined from adsorption studies:

$$\pi = 2\sqrt{(\gamma_S^d\gamma_L^d)} - 2\gamma_{LV} \quad [19]$$

The derivation assumes that the adsorption of vapour is determined solely by dispersion forces (physical adsorption):

$$\gamma_S^d = \frac{(\pi + 2\gamma_{LV})^2}{4\gamma_L^d} \quad [20]$$

It is clearly of interest to compare the surface free energies γ_S^d determined from gaseous adsorption studies with those obtained from contact angle measurements. Fowkes quotes an average value of 122 ergs cm^{-2} for the dispersive energy of a graphite surface, γ_S^d , from the adsorption of N_2 and n-heptane, which compares well with the value of 109 ergs cm^{-2} from contact angle measurements of a water droplet on a graphite surface ($\theta = 85.7^\circ$ and $\pi^0 = 19$ ergs cm^{-2}).

The surface free energies can also be experimentally determined from heats of immersion ΔH_i since:

$$\begin{aligned} \gamma_{SL} - \gamma_S &= \gamma_{LV} - 2\sqrt{(\gamma_S^d\gamma_L^d)} \\ \Delta H_i &= (\gamma_{SL} - \gamma_S) - T \left(\frac{d\gamma_{SL}}{dT} \right) \\ \Delta H_i &= \gamma_{LV} - 2\sqrt{\gamma_S^d\gamma_L^d} \\ &\quad - T \left[\frac{d\gamma_{LV}}{dT} - 2\sqrt{\gamma_{LV}^d} \frac{d\sqrt{\gamma_S^d}}{dT} - 2\sqrt{\gamma_S^d} \frac{d\sqrt{\gamma_{LV}^d}}{dT} \right] \end{aligned} \quad [21]$$

Experimental characterization of interfacial energies – heat of immersion Equation [21] can be used with heats of immersion measured calorimetrically to determine the contribution of polar interactions between the solid and the liquid into which it has been immersed. If dispersion forces only were significant at the interface, then the equality of eqn [19] should hold. Deviations from the equality of eqn [19] referred to as the excess by Fowkes are a measure of the strength of the polar interaction:

$$\text{the excess} = (\pi + \gamma_{LV}) - 2\Phi\sqrt{(\gamma_S^d\gamma_L^d)} \quad [22]$$

Table 2 Polar interfacial interactions at solid-liquid interfaces

<i>Solid</i>	<i>Liquid</i>	$2\sqrt{(\gamma_S^d, \gamma_L^d)}$ (<i>ergs cm⁻²</i>)	$\pi + 2\gamma_{LV}$ (<i>ergs cm⁻²</i>)	<i>Excess</i> (<i>ergs cm⁻²</i>)
Graphite	n-Heptane	96	96	0
	Benzene	114	134	20
Silica	n-Heptane	100	100	0
	Benzene	118	138	20

Table 2 shows polar interactions at some solid-liquid interfaces in terms of the excess.

From the limited data reproduced in table it can be seen that the adsorption of hydrocarbons both on graphite and silica is principally through dispersion forces while that of n-propanol and water on silica show significant polar interactive forces. Clearly, the presence of these strong attractive forces will result in very stable films.

The Forces Between a Charged Particle Surface and an Ionic Solution

Origin of particle surface charge The attraction between a charged surface and a concentration of counterions in the diffuse double layer adjacent to the particle surface will be the source of increased interaction energies. The charge density on the surface of the solid particles, and hence the potential gradients in the diffuse double layers, is determined by the degree to which the intermolecular forces at the crystal surface are non-compensated. These are related to the structure of the crystal lattice and to the orientation of the cleavage planes at the surface.

As a consequence of a surface charge, to a greater or lesser extent hydrated ions will be adsorbed, the energy of attachment being related to the charge density on the particle surface. As both orthorhombic sulfur and graphite exhibit comparatively weak residual surface forces with strong non-polar bonds being localized within the unit cells of the crystal lattice, the attachment energy of hydroxyl and hydrated ions will be low giving the surfaces their hydrophobic character.

On the other hand, for ionic crystals the uncompensated electrostatic forces at the surface may be high and can lead to strong attachment of water. As the electrostatic forces operate over significantly longer distances than do the London-van der Waals

forces they will give hydrated layer thicknesses of the order 20–60 Å. According to Klassen and Mokrousov who quote Derjaguin and Derjaguin, Karasiev and Zorin, the hydrated layer has an increased viscosity over that of the bulk water and the change in viscosity is discontinuous.

Diffuse boundary layer To illustrate the previous observations consider a plane surface with a uniform charge density σ_0 in contact with water with a bulk ionic concentration n_0 . If the solid-water interface has a positive electrical potential, ψ_0 , the potential in the solution will decrease to 0 as one proceeds in a normal direction away from the surface into the solution. Close to the positively charged surface, however, there will be an excess of negative ions. If n^+ and n^- are the concentrations of the positive and negative ions, of equal and opposite charge, $+z$ and $-z$, respectively, at a point in the solution then the net charge density ρ at that point in the solution will be:

$$\rho = ze(n^+ - n^-) \quad [23]$$

Using the Boltzmann factor, the ionic concentrations can be linked to the local potential at a point in the solution:

$$n^- = n_0 \exp\left(\frac{ze\psi}{kT}\right)$$

and:

$$n^+ = n_0 \exp\left(-\frac{ze\psi}{kT}\right)$$

from which:

$$\rho = -2n_0ze \sinh\left(\frac{ze\psi}{kT}\right) \quad [24]$$

The integral of ρ to infinity will give the total excess charge in the solution per unit cross-sectional area which is equal to but opposite in sign to the charge density on the surface σ . The situation is that of a double layer of charge, the one localized on the solid surface and the other in the diffuse region.

To link the potential in the solution with the normal distance x from the surface the Debye-Hückel treatment may be followed. This uses Poisson's equation which relates the divergence of the gradient of the electrical potential at a given point to the charge

density at that point:

$$\nabla^2 \psi = -\frac{4\pi\rho}{D}$$

$$\nabla^2 \psi = \frac{8\pi n_0 z e}{D} \sinh\left(\frac{ze\psi}{kT}\right) \quad [25]$$

where ∇^2 is the Laplace operator and D is the dielectric constant of the medium (for water = 78). For small values of $ze\psi$ with respect to kT , eqn [25] can be expressed as:

$$\nabla^2 \psi = \kappa^2 \psi$$

$$\kappa^2 = \frac{8\pi n_0 z^2 e^2}{DkT} \quad [26]$$

The treatment for a plane charged surface is due to Gouy and Chapman (after defining):

$$y = \frac{ze\psi}{kT} \quad \text{and} \quad y_0 = \frac{ze\psi_0}{kT} \quad [27]$$

Eqn [26] can be written as:

$$\frac{d^2 y}{dx^2} = \kappa^2 \sinh y$$

with the boundary conditions at:

$$x = \infty, y = 0 \quad \text{and} \quad \frac{dy}{dx} = 0 \quad [28]$$

For the case where y_0 is small, for example for univalent ions at room temperature, $\psi_0 < 25$ mV, the

solution of eqn [28] reduces to:

$$\psi = \psi_0 \exp -\kappa h_x \quad [29]$$

setting $x = h_x$ as the separation distance.

The quantity $1/\kappa$ is the distance from the surface where the potential in the solution reaches $1/e$ ($= 0.3679$) of its value at the surface; the plane $1/\kappa$ is used to represent the thickness of the diffuse layer adjacent to the surface. The charge density of the solid surface can be obtained from a knowledge of $\psi(x)$ vs x since:

$$\sigma_0 = - \int_0^\infty \rho \, dx = \frac{D}{4\pi} \int_0^\infty \frac{d^2 \psi}{dx^2} dx$$

$$= - \left(\frac{D}{4\pi} \right) \left(\frac{d\psi}{dx} \right) \Big|_{x=0} \quad [30]$$

For small potentials, the diffuse double layer can be likened to an electrical condenser of charge density σ_0 and a plate separation of $1/\kappa$.

Figure 3 shows very interesting relations between $\psi(x)$ and x and between σ_0 and ψ . Figure 3(A) shows the exponential decay in the solution potential for a surface whose potential ψ_0 is 25 mV, while Figure 3(B) shows that increasing the concentration of the bulk solution of univalent ions, from 0.001 to 0.01 M significantly reduces the dispersion layer thickness from almost 200 to less than 40 Å.

Figure 3(C) shows a reduction of dispersion layer thickness of similar magnitude to that reported in Figure 3(B) following the replacement of a 0.001 M univalent solution by a 0.001 M divalent solution. Figure 3(D) and (E) show the relation between the

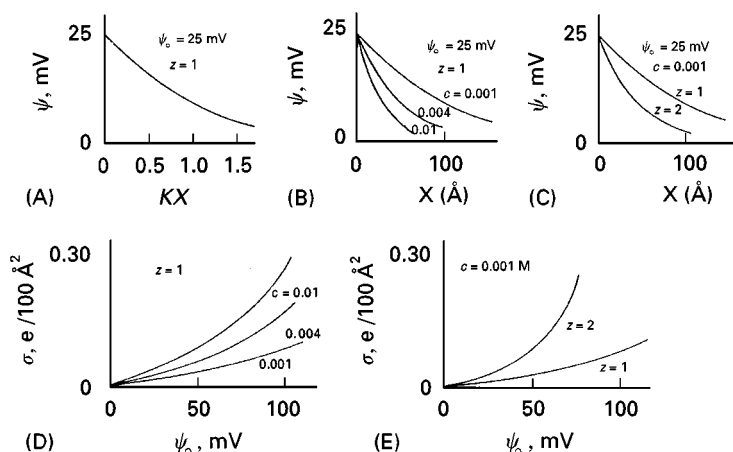

Figure 3 The diffuse double layer. Reproduced with permission from Adamson AW (1982) *Physical Chemistry of Surfaces*, 4th edn. New York: John Wiley.

surface charge density ($e/100 \text{ \AA}^2$) and the surface potential ψ_0 .

Conversion to SI units requires a conversion constant, the permittivity (of vacuum), $\epsilon^0 = 8.859 \times 10^{-12}$ coulombs/(metre volt). The conversion in cgs/esu to SI units of the potential ψ and the charge e is given in eqn [31]:

$$\psi_{\text{cgs/esu}} = \psi_{\text{SI}} \times (4\pi\epsilon^0)^{1/2} \quad \text{and} \quad e_{\text{cgs/esu}} = \frac{e_{\text{SI}}}{(4\pi\epsilon^0)^{1/2}} \quad [31]$$

To illustrate the use of the conversion constant, the interchange energies between two charged surfaces, as given by Coulomb's law, are:

$$\begin{aligned} \text{in CGS units} \quad \epsilon(\text{ergs}) &= \frac{q_1 q_2}{h_x D} \\ \text{in S.I. units} \quad \epsilon(\text{Joules}) &= \frac{q_1 q_2}{4\pi\epsilon^0 h_x D} \end{aligned} \quad [32]$$

The equivalent equation in SI units to eqn [26] then becomes:

$$\nabla^2 \psi = \frac{2n_0 z^2 e^2}{\epsilon^0 D k T} \psi = \kappa^2 \psi \quad [33]$$

To illustrate the magnitude of κ , consider a 1 mM solution in water of a uni-univalent solute. In this case the number of molecules, n_0 , of solute per cubic metre is just the Avogadro number, $N_0 = 6.02 \times 10^{23}$. Note also that $\epsilon^0 D$, sometimes written only as D , is $= 6.91 \times 10^{-10}$ coulombs/(volt metre). Substituting parameters for this case in the relationship for κ implied in eqn [33], a value for κ of $1.0 \times 10^8 \text{ m}^{-1}$ is obtained, or $1/\kappa = 10 \text{ nm}$.

The Stern treatment of the electrical double layer
The Gouy–Chapman treatment gives absurd answers for small values of κh_x when ψ_0 is large. Adamson illustrates this point with the example for $\psi_0 = 300 \text{ mV}$:

$$y_0 = \frac{300}{25.69} = 12 \quad [34]$$

if $n_0 = 0.001 \text{ M}$ then $n^- = 0.001 \times e^{12} = 160 \text{ moles/litre!}$ This is due to the treatment of the charges as point sources by neglecting the ionic diameters.

Stern suggested that the region in the liquid adjacent to the surface be divided into two parts, an inner compact layer consisting of ions or hydrated

molecules which are firmly attached to the surface, and an outer diffuse layer in which the ions were less firmly bound. The key to his analysis is the estimation of the extent to which solute molecules will enter the compact layer, which requires them to displace water dipoles, in particular.

If S_0 is the number of occupiable sites on the surface then the maximum charge density for the compact layer is $\sigma_0 = zeS_0$. In the presence of a dilute solute phase, however, the ratio of the sites occupied by the solute to those potentially occupiable is proportional to, N_s , the mole fraction of solute. In dilute solution, Stern linked this fraction and the potential ψ_δ at the outer surface of the compact layer to a charge density σ_s in the compact layer, with ϕ allowing for any additional chemical adsorption potential. This approximates to:

$$\frac{\sigma_s}{\sigma_0} = \frac{N_s \exp[-(ze\psi_\delta + \phi)/\kappa T]}{1 + N_s \exp[-(ze\psi_\delta + \phi)/\kappa T]} \quad [35]$$

This suggests that the charge σ_s in the compact layer can be linked to the potential at its outer boundary ψ_δ , using eqn [30] with the approximation:

$$-\left. \frac{d\psi}{dx} \right|_0 \approx \frac{\psi_0 - \psi_\delta}{\delta} \quad \text{hence} \quad \sigma_s \approx \frac{D'}{4\pi\delta} (\psi_0 - \psi_\delta) \quad [36]$$

where δ is its thickness and D' is an apparent dielectric constant for the layer.

In the diffuse layer as one proceeds outwards from the surface a potential at position x can be calculated using eqn [29] with ψ_δ replacing ψ_0 . The ions are mobile in this layer and the layer is characterized by a thickness $= 1/\kappa$.

The electrodynamic potential (ζ) A charged surface experiences a force in an applied electric field. As it moves the boundary of the water moving with it is the shear plane of thickness $1/\kappa$, which has a potential $\psi(1/\kappa)$, commonly referred to as the zeta-potential (ζ).

The potential of the shear plane can be experimentally determined by electrophoresis. If for a spherical particle of radius R_p , the charge density of the diffuse layer up to the shear plane is σ_D , the force exerted on it in an electric field of $F_s (\text{V m}^{-1})$ will be:

$$f_E = \sigma_D \times F_s \times 4\pi R_p^2 \text{ (newtons)} \quad [37]$$

this will cause it to move at a velocity at which the viscous drag is equal to the applied electrical force. From Stokes' law the shear resistance f_s , of a particle

of radius R_p , moving at a velocity v is given by:

$$f_s = 6\pi\mu R_p v \quad \text{which gives} \quad v = \frac{2\sigma_D F_s R_p}{3\mu} \quad [38]$$

The relation between the charge density, σ_D , of the diffuse layer and the potential at the shear plane treated as a parallel plate condenser with plates $1/\kappa$ apart in SI units is:

$$\sigma_D = \varepsilon^0 D \zeta \kappa \quad (\text{coulombs m}^{-2}) \quad [39]$$

If the ζ -potential of a spherical particle, of radius $1\mu\text{m}$ moving in an external field of 1V cm^{-1} is 25mV , then the velocity calculated from eqns [38] and [39] is $1.15 \times 10^{-6}\text{ m s}^{-1}$. Data quoted by an equipment manufacturer gives a velocity $v = 2.0 \times 10^{-6}\text{ m s}^{-1}$, for the same conditions.

The charge density σ_D of the diffuse layer follows from the ζ -potentials measurements. The charge density of the surface, σ_0 , follows as the sum of the charge densities of the compact layer σ_s and σ_D .

Collectors

General A collector is a surface-active chemical which has a polar and a non-polar group. The work of adhesion of a collector to a solid surface has been separated into three components by Leja:

$$w_{SLV} = w^d + w^b + w^i \quad [40]$$

where w^d is the dispersive component, w^b is the energy associated with polar adsorption of water at non-ionic sites and w^i is the contribution through electrostatic interactions with the Stern layer associated with the solid surface (Figure 4).

The collector molecule must be firmly attached to the solid surface through its polar group and must be able to confer sufficient hydrophobicity to the surface through the non-polar component to facilitate bubble attachment. It appears that for effective attachment, multilayer adsorption is required. Fuerstenau and Fuerstenau have suggested that the multilayer arise from the dispersive interactions between the non-polar parts of the molecules; they have referred to the resulting structure of the adsorbed layer as hemimicelles.

The attachment of a bubble to the solid ultimately involves an interaction between the polar groups adsorbed on the bubble surface and the multilayered collector on the particle's surface. As the science of the interactions is still imperfectly understood it is

Figure 4 The Stern layer. Reproduced with permission from Adamson AW (1982) *Physical Chemistry of Surfaces*, 4th edn. New York: John Wiley.

necessary briefly to review the nature of the collector in specific separations.

Thiol collectors The discovery of xanthates in the 1920s caused a rapid increase in the flotation process generally, but specifically with nearly all the sulfide ores. While they confer hydrophobicity on sulfide minerals, they do not affect the flotation of silicates, aluminosilicates, oxides or mineral salts. However, to achieve selective separation between sulfides within the same ore-body careful choice of reagent and control of operating conditions is required.

Although there appears to be a wide range of these sulfur-bearing compounds, they are derived from a restricted number of oxygen-bearing compounds through the substitution of sulfur for the oxygen. The great majority are derived from carbonic, carbamic and phosphoric acids, urea and the alcohols. They are usually surface-active with respect to the liquid-solid interface, but less so at the bubble-liquid surface. Some of the most important of these sulfhydryl collectors are discussed below, with their structures given in Figure 5(A). In all cases R denotes a non-polar group.

Alkyl dithiocarbonates or xanthates ($R-O-CS_2^- M^+$) Potassium ethyl xanthate (KETX) is used for the selective flotation of Cu-Zn, Pb-Zn and Cu-Pb-Zn sulfides. The effective recovery of the sulfide increases with the length of the alkyl group R; n- and iso-propyl and butyl giving increased recovery over the ethyl homologue but with a reduced selectivity. These conflicting trends increase up to amyl and hexyl. All the xanthates mentioned are soluble in water and are restricted to a pH range of 8–13 as they undergo hydrolysis under more acid conditions.

(A) Sulfhydryl collectors

Alkyl dithiocarbonate K^+ xanthates,
R denotes a non-polar group

Dialkyl dithiocarbamate, $(R_1, R_2)N-CS_2^-M^+$

Dialkyl thiourea, $(R_1NH-, R_2NH-)C=S$

Dialkyl and diaryl thiophosphates
 $(R_1-O-, R_2-O-)PS_2^-M^+$

Alkyl mercaptans, $R-S-H$

(B) Anionic collectors

Sulfonated carboxylic acids

Alkyl sulfuric acid and salts

Alkyl phosphoric acid and salts

Figure 5 Industrial flotation reagents.

Dialkyl dithiocarbamate $(R_1, R_2)N-CS_2^-M^+$ These are selective collectors for Cu or Cu-activated Zn from FeS_2 . They are sparingly soluble and are used as emulsions in the pH range 4–9. The non-polar group R_1 is usually CH_3 or C_2H_5 while R_2 is either propyl or butyl.

Dialkyl thiourea $(R_1NH-, R_2NH-)C=S$ These are selective collectors for Cu, Pb and Ag ores and have been used in the flotation of complex Cu–Pb–Zn ores. They are not water soluble and have to be used as dispersions in water.

Dialkyl and diaryl thiophosphates $(R_1-O-, R_2-O-)PS_2^-M^+$ The di-ethyl and di-sec-butyl derivatives are used as collectors for Au, Ag and Cu. The dicresyl derivative is used for Ag, Cu, Pb and Zn. Generally, the dithiophosphates (DTP) reagents are more selective than the xanthates particularly in preventing the flotation of iron sulfides. The alkyl derivatives are water-soluble and are used in 5–20% solutions over the pH range 4–12. The most common alkyl homologues are diethyl and dibutyl. The alkyl derivatives are essentially non-frothing.

The aryl derivatives are dicresyl and exhibit frothing behaviour. They are not water soluble and are used undiluted.

Alkyl mercaptans $R-S-H$ Only homologues higher than C_{12} have been used. Dodecyl mercaptan is a powerful non-selective collector particularly for Cu. The mercaptans are not water soluble and are

used either in an organic solution or as a liquid emulsion.

Xanthate derivatives $R-O-S_2^-M^+$ These are used mainly in Cu flotation. They are water insoluble and are used either as an aqueous emulsion or as an organic solution. They are effective over a wide pH range.

Anionic collectors These are ionizable non-thio compounds derived from carbonic, sulfuric, phosphoric, phosphonic and arsonic acids (Figure 5(B)). They are anionic, depending on the pH of the flotation pulp and are used to collect a wide range of oxide, silicate and salt-type minerals. These minerals usually have positive ζ -potentials and consequently bind OH^- ions giving them a hydrophilic character. For the adsorbed surface to become hydrophobic the non-polar part of the anionic collector molecules must have longer carbon chains than those of the thiols. Their attachment is primarily through electrostatic interactions between the polar group of the collector and the particle surface while dispersive interactions between the non-polar groups of adjacent collector molecules increase the hydrophobicity of the surface by producing multilayered adsorbed films.

Fatty acid salts $R-COO^-M^+$ The cation M^+ is either Na^+ or K^+ , with very few exceptions they operate at high pHs where they are highly dissociated.

The non-polar radical R most used lies in the C_{16} – C_{18} range, typically oleic, linoleic and linolenic.

Unsaturated molecules are preferred. At alkaline pH the metal salts are soluble in water. They are used for the flotation of apatite, calcite, fluor spar and barite. Because of the electrostatic nature of their adsorption they are very powerful collectors for surfaces with positive ζ -potentials but selectivity is difficult to effect and requires careful control of the chemical environment which usually requires the use of depressants.

Alkyl sulfuric acid and salts $R-O-SO_3^- M^+$ These are stronger acids than the fatty acids and exist in an ionized water-soluble form above pH 1–2; the alkyl radical is usually C_{12} and saturated. Organic sulfates and sulfonates are used to float oxides and silicates such as iron ores, chromite, garnet, beryl and zircon. As the bonding with the solid surface is primarily electrostatic, pH control is critical, especially for the shorter chain length alkyl groups, as it affects their intermolecular dispersive bonding.

Alkyl and aryl sulfonic acid and salts $R-SO_3^- M^+$ A typical collector of this type is sodium dodecyl benzene sulfonate $C_{12}H_{25}-C_6H_4-SO_3^-O^-Na^+$ which is a strong acid and will operate in pulps with pH values above 2.

Alkyl phosphoric acid and salts $(R_1O-, R_2O-)PO_2^- M^+$ R_1 and R_2 can be either aliphatic or aromatic. Dialkyls are more strongly frothing than the monoalkyls. They are used in separations from quartz gangue, in particular for the separation of heavy minerals from glass sands. They have also been used in flotation of tungsten, uranium and phosphate ores. They are not selective in the presence of apatite, calcite, fluor spar or barite.

Cationic collectors This group consist of amines which below ceratin pH values exist in the cationic form, RNH_2 , R_1R_2NH , $R_1(R_2)_2N$. The amines are insoluble in the free base form but are treated by acids such as acetic or hydrochloric to solubilize them. They ionize in aqueous solutions as follows:

Typical collectors of this type are a primary aliphatic amine, n-amylamine ($C_5H_{11}NH_2$), a primary aromatic amine, aniline ($C_6H_5NH_2$), and pyridine (NC_5H_5), nitrogen in a benzene-like nucleus.

Particularly important are the quaternary ammonium salts, $R_1(R_2)_3N^+X^-$, which ionize strongly and are water soluble. The collecting action of this group is based on being strongly attached to surfaces with negative ζ -potentials and are consequently rarely selective but are effective over a wide pH

range. Important collectors of this type include alkyl propylenediamine, $(RNH_2(CH_3)_3NH_3)^{2+} 2X^-$, and tetradecyltrimethylammonium bromide (TTAB), $CH_3(CH_2)_{13}-(CH_3)_3-N^+ Br^-$.

Cationic collectors are used to separate sylvite (KCl) from halite (NaCl) in brine and are also used in the separation of silica from phosphate and in the flotation of zinc carbonates and silicates.

The Mechanism Associated with the Flotation of Some Important Ores

Sulfides – recovery of galena – effect of collectors

Most data are associated with the flotation of the lead ore galena PbS , which has been studied extensively. Although the tonnage of lead ore processed is only a tenth of the amount of the copper ores processed (Table 1), the fact that it exists in only one valence state simplifies data interpretation. The overall mechanism for copper sulfide ore processing is accepted as being similar to that of lead despite the copper valence change under oxidizing conditions. Both copper and lead are floated with sulfhydryl collectors and it is of interest to review the concepts associated with the collector action. It is often the case that, despite the high selectivity of the sulfhydryl collectors for sulfides in the presence of oxide and silicate gangues, that further selectivity between different sulfide minerals is required. It is consequently not necessarily sufficient to determine optimum recovery for a specific collector, but it is also necessary to investigate its effect on the simultaneous recovery of an undesired sulfide mineral.

The effect of oxygen on the ζ -potential and KETX adsorption on a galena surface In the absence of oxygen the adsorption density of ethyl xanthate is independent of pH and remains constant at a level of 2×10^{-6} g moles/g of galena, which corresponds to effectively a coverage of a monolayer assuming one xanthate ion adsorbed at one lead site on the surface. The area occupied by an anion of amyl xanthate disposed perpendicularly to the surface of a mineral is given by Klassen and Mokrousov to be 28 \AA^2 . This adsorption area should be independent of the length of the hydrocarbon chains of normal xanthates.

However, the adsorption density does fall as the length of the alkyl chain increases to about half the monolayer adsorption density with octyl xanthate. Additionally, in the absence of both oxygen and xanthate, the ζ -potential vs pH curve for galena, falls from +20 mV at pH 2 to –40 mV at pH 12. The pH at which the ζ -potential is zero is called the point of zero charge (PZC) which is a useful characterizing parameter.

In the presence of 1×10^{-3} molar ethyl xanthate the ζ -potential remains steady at -40 mV over the pH range of 4–12.

This seems to indicate that the attachment is due to the chemisorption of the alkyl part of the xanthate molecule on the galena surface, presumably after displacing H_3O^+ or OH^- ions. The unchanged outer negatively charged compact surface layer is associated with the polar end of the molecule.

In the presence of oxygen, but without xanthate, the ζ -potential vs pH differs significantly from the previous case. Over the pH range from 4 to 6 the ζ -potential vs pH curve is convex upwards with a maximum of just under $+20$ mV at pH 6. At increasing pHs the ζ -potential falls to 0 at pH 6.9, the PZC; from 6.9 to 12 it falls from 0 to -40 mV. It should be noted that for the previous case of no oxygen and no xanthate the pH at the PZC is 2.6.

In the presence of 1×10^{-4} mol L^{-1} ethyl xanthate and oxygen, the ζ -potential–pH curve is again electronegative over the range 4–12, as with the case for xanthate without oxygen, but is no longer constant, falling from -20 mV at pH 4 to -40 mV at pH 12.

There are conflicting explanations for the effect of oxygen on the galena surface. One plausible theory is that, in the presence of oxygen, the surface is oxidized to thiosulfate and sulfate. As air also contains CO_2 , lead carbonates may also form displacing the sulfates. Some of these surface compounds may move into the inner compact layer in the solution. In the presence of xanthates, a significant xanthate fraction may react directly at the surface, possibly with the sulfates, forming a strong bond with the lead mineral. The rest of the xanthate will displace the sulfate from the inner to the outer compact layer, causing the potential at the outer compact layer ψ_δ to remain electronegative.

It is further postulated that with excess xanthate, metathetic replacement of the sulfate will occur producing uncharged hydrophobic, insoluble lead ethyl xanthate. This process is clearly kinetic requiring diffusion of the unreacted sulfate at the surface through the compact layer. Multiple layers of the insoluble lead ethyl xanthate will confer increased flotability on the galena. Finkelstein, Allison, Lovell and Stewart reported improved flotation recoveries for galena using ethyl xanthate in terms of the thickness of the lead ethyl xanthate layers expressed as monolayers. The recovery increased from zero with no ethyl xanthate to 70% for a single monolayer increasing to 95% with five monolayers.

Selective flotation of galena – effect of depressants
Reagents which, to a greater or lesser degree depress

recoveries of sulfides (depressants), include OH^- , S^{2-} and chromate.

Fuerstenau in 1982 reported 100% recovery of galena, using 1×10^{-5} mol L^{-1} ethyl xanthate in the presence of oxygen, over the pH range 2–10. However, if the lead content (grade) of the concentrate is required to be low in the presence of other sulfides, which are themselves being floated by the 1×10^{-5} mol L^{-1} ethyl xanthate, this requires a reduction (depression) of the galena recovery simultaneously with a smaller reduction in the recovery of the desired sulfide.

Depression of galena using hydroxyl is effected at pH values greater than 11, due to the formation of HPbO_2 , which is the unhydrated form of $\text{Pb}(\text{OH})_3^-$, in the Stern compact layer, this causes the galena surface to become hydrophilic with consequent reduction in lead recovery.

The depression of galena using sodium sulfide is much greater than that of all other sulfide minerals. Additions of sodium sulfide to a galena suspension in xanthates will cause an insoluble hydrophilic lead sulfide rather than lead xanthate to form at the solid surface according to the reaction:

In the presence of chromate the adsorption of xanthates does not decrease, but when lead chromate forms on the surface, the hydration of the chromate is so strong that the collector hydrophobicity is significantly reduced.

Grade-recovery of copper ores In view of the economic importance of chalcocite (Cu_2S) and chalcopyrite (CuFeS_2) their selective recovery from ores containing undesired pyrites will be briefly reviewed.

Depression of pyrite – Effect of pH. Flotation of pyrite will be possible with short-chain xanthates such as potassium ethyl xanthate at pHs below 11. At addition rates of 2×10^{-4} mol L^{-1} of KETX , 100% recovery is possible. The recovery is thought to be due to the adsorption of dixanthogen on the surface. However, at high pH values xanthate oxidation to dixanthogen does not occur according to the reaction shown below, thus depressing the pyrite recovery:

Effect of CN^- . Pyrite is significantly depressed by KCN . In the absence of KCN pyrite recoveries of 100% are obtained at pH below 7, using 1×10^{-4} mol L^{-1} KETX . Significant amounts of

pyrite are still present in the concentrate even up to pH 10. However, with a KCN addition of $6.0 \times 10^{-3} \text{ mol L}^{-1}$, recovery is significantly depressed at pH 4 and completely depressed above pH 7.

Effect of pyrite depressants on copper recovery
To assess the selective separation of copper ores from pyrite it is necessary to see how the copper floats under conditions identical to those reported for pyrite depression.

Chalcocite will float completely at up to pH 10 using 5.0×10^{-5} ethyl xanthate. The mechanism of flotation in the presence of amyl xanthate is similar to that of galena, with a chemisorbed cuprous amyl xanthate after which further xanthate additions form multilayers of cuprous xanthate in the compact layer, increasing the overall hydrophobicity.

At pHs between 8 and 10, the addition of sodium sulfide will depress pyrite without significantly altering the chalcocite recovery. The most effective depressant for this separation does however appear to be potassium cyanide which hardly affects the chalcocite recovery between pH 8 and 12 while virtually completely suppressing the pyrite over this range.

Chalcopyrite will float at 100% recovery over the pH range 2–12 both with $1 \times 10^{-5} \text{ mol L}^{-1}$ ethyl xanthate and $1.3 \times 10^{-5} \text{ mol L}^{-1}$ dioxanthogen. No depression in recovery is observed up to pH 13. From this it may be inferred that at these high pHs it is the stability of the cuprous ethyl xanthate which effects flotation.

As chalcopyrite contains iron it is to be expected that it will to some extent be affected by the pyrite depressants but will be less sensitive to NaCN additions than the pyrite. For example, in a system where 60.9% pyrite recovery was achieved simultaneously with 90.5% chalcopyrite recovery with no depressant at pH 8.8, the addition of 0.04 kg ton^{-1} NaCN changed these figures to 26.1% pyrite recovery and 84.2% chalcopyrite recovery. Further additions of cyanide reduced the pyrite recovery to 15.6%, but also cut the chalcopyrite recovery to 31.0%.

Finally, it should be noted that sodium sulfide will depress chalcopyrite more than pyrite. This is due to the preferential formation of cupric sulfide over that of cuprous ethyl xanthate.

Flotation of oxides and silicates Oxides and silicates are the most abundant minerals in the earth's crust. Their flotation behaviour is important both because of their inherent value and because they act as gangue in the flotation of other minerals. Once again only a sample of the separations of interest can be discussed. Consider firstly the separation of quartz from haematite in iron ore processing.

Fuerstenau and Healy have suggested six possible procedures, four of which have been successfully employed in industry. These are based on the ζ -potential for haematite being positive in the pH range 2–4 with a PZC in the region of pH 6, while for quartz over the same range the ζ -potential is negative with a PZC at pH 2.

These procedures are:

- Flotation of haematite using an anionic sulfonate collector, for example sodium dodecyl benzene sulfonate which will adsorb on the positively charged haematite surface but not on the negatively charged quartz.
- Flotation of the haematite by the chemisorption of a fatty acid collector at pH 6–8. Chemisorption on the quartz will not occur because of its large negative ζ -potential at this pH.
- Reverse flotation of quartz at pH 6–7 using a cationic collector, for example, amylamine which will adsorb on the highly negatively charged quartz but not on the essentially uncharged haematite.
- Reverse flotation of quartz activated with calcium ions, with a long-chain fatty acid collector and the haematite depressed through the addition of starch. The hydrophilic starch molecules will chemisorb on the haematite through their carboxyl groups. Without the starch the haematite would also float under these conditions.

The successful implementation of these separations is clearly consistent with the electrostatic theory of collector adsorption.

Further thoughts on the electrostatic model of flotation. For collectors to function through physical interactions they must be present as counterions in the compact layer. Under these conditions the net charge on the outer boundary of the diffuse layer is reduced and hydrophobic interactions with the non-polar surfactants on the bubble surface can occur. Iwasaki *et al.* reported very interesting results relating to the flotation of goethite (FeOOH). Goethite has a PZC at pH 6.7 and they measured flotation recoveries, in a laboratory Hallimond tube, as a function of pH using $1.0 \times 10^{-3} \text{ mol L}^{-1}$ of the anionic collectors sodium dodecyl sulfate and sodium dodecyl sulfonate and the cationic collector dodecyl ammonium chloride. They achieved effectively 100% recoveries up to pH 6.0 using the anionic collectors with the recovery falling effectively to zero above pH 7.0.

The recovery of goethite vs pH using the $1.0 \times 10^{-3} \text{ mol L}^{-1}$ cationic dodecylammonium chloride was the inverse of this with virtually no recovery up to pH 6.0 and 100% recovery between

pH 8 and 12.2 when the recovery fell to zero because the quaternary ammonium salt hydrolysed to the parent amine.

The increased flotation response at lower pHs with the anionic collectors is associated with an increased charge density σ_s in the compact layer which causes larger amounts of collector to be present as counterions. The increased concentration of their non-polar groups in the compact layer will increase the particle's hydrophobicity.

Modi and Fuerstenau reported tests on corundum (Al_2O_3), which has a PZC at pH 9, at four different pH values using an anionic collector, sodium dodecyl sulfate, at concentrations ranging between 10^{-7} and 10^{-1} mol L $^{-1}$.

At pH 4.0, 100% recovery was achieved with 0.5×10^{-4} mol L $^{-1}$, but it required 10 times that concentration for 100% recovery at pH 6.0, while at pH values of 9.3 and 11.0 the highest recovery achieved was only 30% at a reagent concentration of 10^{-3} mol L $^{-1}$.

Effect of the length of the hydrocarbon chain on the collector performance. Data have been reported for the flotation of quartz (PZC at pH 2.0) at pH 6–7, using the cationic alkylammonium acetates, with the alkyl chain length varying between C_4 and C_{18} . Incipient flotation occurs from about 10^{-8} mol L $^{-1}$ for C_{18} to 10^{-1} for C_4 . Similarly high rates are observed at 10^{-6} mol L $^{-1}$ for C_{18} to 0.5 mol L $^{-1}$ for the C_4 . The onset of the high flotation rates are equated to the onset of hemimicelle formation.

Frothers

Chemical types A frother is a surface-active chemical whose principal function is to increase significantly the dispersion of air at a given aeration rate in the pulp phase of a flotation machine by producing small bubbles; this is done through the reduction of the surface tension at the air–water interface. If the pressure of the dispersed air is p_0 and the hydraulic pressure in the liquid at the aerator is p_b then the bubble radius R_b will be:

$$R_b \approx \frac{2\gamma}{(p_0 - p_b)} \quad [41]$$

Laskowski has reviewed the mechanism of the action of surface-active reagents in flotation. He said that frother molecules have an uneven distribution of polar and non-polar groups which cause them preferentially to orientate at the air–water interface with the polar groups forming a liquid film around the bubble by hydrogen bonding with the water and the non-polar groups forming a gaseous film within

the bubble. They may be classified into five groups:

1. Aliphatic alcohols with a single hydroxy group R–OH, where R is either a straight-chain alkyl group with five to eight carbon atoms or a branched chain with six to sixteen carbon atoms. Typical of the branched alcohols are methyl iso-butyl carbinol (MIBC), di-acetone alcohol and 2-ethyl hexanol. These frothers produce fine-textured, fairly selective froths.
2. Cyclic alcohols. These are represented by pine and eucalyptus oils of which the active components are the terpene alcohols typically α -terpineol. These are traditional frothers and are still used usually in combination with other frothers and collectors in 30% of the world's copper concentrators.
3. Phenols of which cresylic acid a mixture of cresols and xylenols, is the most commonly used.
4. Alkoxyparaffins of which the most successful is 1,1,3-triethoxybutane, have come into use in sulfide flotation as they seem also to have collector specificity.
5. Finally the polyglycols, particularly polypropylene glycol, these are available as commercial products with the general formula $\text{R}(\text{X})_n\text{OH}$, where R is either H or $\text{C}_m\text{H}_{2m+1}$ and X is either ethylene oxide (EO) $-\text{CH}_2\text{CH}_2\text{O}-$, propylene oxide (PO) $-\text{CH}_2\text{CH}(\text{CH}_3)-\text{O}-$ or butylene oxide (BO) $-\text{CH}_2\text{CH}_2\text{CH}(\text{CH}_3)-\text{O}-$. In the PO and BO frothers the propylene and butylene groups are hydrophobic and the ether oxygen and the hydroxyls are hydrophilic. Varying the relative length of the hydrophobic to hydrophilic groups in the molecule permits tailoring the molecule to a specific application.

Bubble stability in pulp The crucial property of a bubble in an aerated flotation cell relates to its ability to survive the collision and attachment of a particle without bursting. Although it is possible to observe that the addition of frothers does increase the stability of a single bubble, a coherent quantitative stability model does not exist. This will need to relate to the ability of its water film surrounding the bubble to withstand local disturbances. This ability is thought to be related to dynamic changes in surface tensions in the film following the local decreases in frother concentration after distortion has occurred following impact with a particle.

The effect of frother concentration on the surface energy of the solution has been used by Laskowski to characterize the surface activity of various frothers as related to their molecular structure. This is based on the application of the Gibbs adsorption isotherm, where Γ is the surface excess of the surface-active

agent, a its activity in the bulk solution and γ_{LV} is the bubble-liquid interface energy:

$$\Gamma = -\frac{a}{RT} \times \frac{\partial \gamma_{LV}}{\partial a} \quad [42]$$

This implies that a decrease in a , the surfactant activity, at the gas-liquid interface following local surface increases, will be associated with a very sensitive surface tension γ increase.

Bubble-Particle Collision Dynamics

Interception efficiency – single bubble – particle collision Flint and Howarth observed that for a rational basis for flotation cell design to be achieved it is necessary that methods for the prediction of bubble-particle collision and subsequent adhesion be available.

For a single particle falling under gravity in the path of a single rising bubble, they provided a general definition of collision efficiency E , as the ratio of the number of particles which collide with the bubble to the number that would have collided if the liquid streamlines had not been diverted by the bubble. Their analysis is based on calculating the trajectories of single particles, initially remote from the bubble, and which are a distance δ from the centreline of the path of the rising bubble (Figure 6). Although all the liquid will pass around the bubble, particles on streamlines which pass closer to the bubble than the radius of the particle, are deemed to have come into contact with the bubble.

Calculation of single particle trajectories The bubble and particle are both assumed to be spherical, with the bubble of radius R_b rising vertically at a velocity U , and the particle of radius R_p falling under gravity. The trajectory calculation begins at a point where the lateral components of the flow field ahead

of the rising bubble begin to induce a sideways motion of the particle. At this point the particle is considered to be offset by a distance, δ , from the centreline of the rising bubble.

The consequence of the flow field assumed by the authors is that the trajectory is defined by the initial δ . A grazing trajectory is defined where for particles with an initial offset δ_0 , the trajectory passes at a distance R_p from the bubble shell on its horizontal diameter. For particles at smaller offsets, contact will be made at some point on the bubble shell, while those with $\delta > \delta_0$ will make no contact.

The collision efficiency then follows:

$$E = \frac{\delta_0^2}{(R_b + R_p)^2} \quad [43]$$

The particle trajectories under the influence of gravity and the flow pattern ahead of the rising bubble can be computed by integrating eqn [44] with the initial offset δ as a boundary condition. The liquid flow field ahead of the rising bubble is described in two dimensions, y (vertical) and x (horizontal), by its local velocity components u_y and u_x (assuming axisymmetric flow) using either the Stokes' or the potential flow stream functions. As the particles are very small ($R_p < 100 \mu\text{m}$) consideration of the interaction between the flow fields of particle and fluid is not necessary. The motion of the particle is described by its velocity components v_y and v_x .

The velocity components are normalized by dividing by U and setting the dimensionless time $t^* = tU/R_b$. The equations can then be expressed in terms of the dimensionless parameters K and G , where $K = (2\rho_p R_p^2 U)/(9\mu_f R_b)$ which is directly related to the ratio of inertial to drag forces on the particle while $G = (2[\rho_p - \rho_f]R_p^2 g)/(9\mu_f U)$ represents the terminal settling velocity of the particle in an undisturbed fluid:

$$K \frac{\partial v_x^*}{\partial t^*} = u_x^* - v_x^* \quad [44]$$

$$K \frac{\partial v_y^*}{\partial t^*} = -G - u_y^* + v_y^*$$

Although this treatment greatly oversimplifies the flow processes in a highly aerated well-stirred suspension of particles in water, it does make interesting statements about the effects of bubble size on the efficiency of collection of a single particle of a given size and density.

Flint and Howarth report the fractional collision efficiency, E , as a function of the parameters K and G . For K values less than 0.1 E is a function of G only

Figure 6 Single particle trajectory in the region of a rising bubble. Reproduced with permission from Flint and Howarth (1971) The collision efficiency of small particles with spherical air bubbles. *Chemical Engineering Science* 26, 1155-1168.

according to:

$$E = \frac{G}{G + 1} \quad [45]$$

The upper limit of $K = 0.1$ corresponds for example to a situation of 20 μm particles in an aerated suspension of 0.2 mm bubbles. Bubbles of this size will rise through still water at $U = 5 \text{ cm s}^{-1}$. K for silica, chalcopryrite and galena under these conditions is respectively 0.06, 0.095 and 0.17; the corresponding G values are 0.028, 0.055 and 0.11.

Using eqn [45], the respective collision efficiencies are 0.027, 0.052 and 0.10. If the bubbles in the aerated suspension were larger, the collision efficiencies would drop. For example for 0.4 mm bubbles whose rise velocity $U = 10 \text{ cm s}^{-1}$, the K values would fall further below 0.1 and the G values would also fall to 0.014, 0.027 and 0.055 with corresponding E values of 0.014, 0.026 and 0.052.

Thus, while 0.4 mm bubbles are probably satisfactory for floating chalcopryrite and galena, it might be necessary to generate smaller bubbles to float silica selectively. However, 60 μm silica particles will be efficiently floated with 1 mm bubbles. The bubble size required for the effective flotation of 60 μm chalcopryrite and galena need be no smaller than 5 mm.

These observations are obviously of both technical and economic importance, as while it is unnecessary to generate small bubbles for medium-size sulfide mineral particles, for light silicate mineral particles it may be necessary for selective separation to aerate the pulp suspension down to 100 μm microbubbles.

Bubble-particle contact time – general Following initial interception of the particle by the bubble, two possible modes of contact have been proposed.

First, the bubble shell is considered to deform elastically and for the particle either to attach to the bubble, or ultimately to be expelled from the shell under the elastic forces. The contact time is that lapsing between the moment of initial contact when the surface begins to deform, to the time when it first regains its original undistorted shape, subsequent oscillations being ignored.

In the second technique the particle after collision with the bubble is assumed to remain in contact with an undeformed surface, while being swept around from the point where it initially made contact, until it approaches the bubble's wake, where it is detached from the shell. The contact time according to this method is the time lapsed between the original contact to that when it first enters the bubble's wake.

Contact time assuming bubble – shell deformation Ye and Miller developed a model based on estimating the penetration distance $h(t)$ of a particle into the bubble shell. **Figure 7** shows their concept of defining $h(t)$ for the special case when contact is made on the line of centres. The deformed area increase is approximated in terms of $h(t)$ as:

$$A(t) = \pi h(t)^2 \quad [46]$$

The force resisting the motion of the particle after collision is described in terms of the increase in the surface free energy of the deforming bubble surface:

$$dG_A = \gamma dA(t) = 2\pi\gamma h(t)dh(t) \text{ and the resisting force}$$

$$F(t) = \frac{dG_A}{dh(t)} = 2\pi\gamma h(t) \quad [47]$$

The particle and the bubble approach each other at a relative velocity v^* . The position of the initial point of contact by the particle at the bubble surface is defined by an angle α between the contact point and the bubble centre and the centreline of the rising bubble.

The deformation is presumed to occur along the radial angle α at a relative velocity v_b^* . After impact the motion of the particle is resisted by the deforming bubble surface and is decelerated to zero. It is then accelerated in the reverse direction by the shell tension until it reaches the local bubble velocity, at which time it is presumed to lose contact with the

Figure 7 Bubble-particle contact time. Reproduced with permission from Ye and Miller (1988) Bubble/particle contact time in the analysis of coal flotation. *Coal Preparation* 5, 147–166.

bubble. If, however, the water film between the particle and the bubble during the deformation is thinned to the point of rupture then attachment will follow.

By assuming an average touching angle of $\sin^{-1}(2/3)$ they quote, for the overall contact time τ in seconds:

$$\tau = 13.5 \times \sqrt{\left(\frac{\pi \bar{m}_b m_p}{\gamma(\bar{m}_b + m_p)} \right)} \quad [48]$$

Figure 8 shows contact times calculated using eqn [48] for a particle with a specific gravity of 2.6. It can be seen that if the particle mass is very much greater than the effective bubble mass then the contact time depends only on the bubble size.

Contact time assuming sliding contact Dobby and Finch have developed a model to predict contact time following an initial particle–bubble shell contact, at an angle α_n with respect to the centre of the bubble. The particle is pressed against the shell surface by its settling velocity $v_T \cos \alpha$ in the inward direction to the bubble centre while it is also being driven tangentially by the liquid moving in close contact with the bubble shell, at a velocity u_x . It leaves the shell at an angle α_m at which point its inward radial motion is equal the outward radial component of the surface liquid. The particle contact time t_s follows from the length of

Figure 8 Particle bubble contact times. Reproduced with permission from Ye and Miller (1989) The significance of bubble/particle contact time in the analysis of coal flotation. *International Journal of Mineral Processing* 25, 199–219.

Figure 9 Particle bubble sliding contact times. Reproduced with permission from Dobby and Finch (1985) A model for particle sliding time for flotation size bubbles. *Journal of Colloid and Interface Science* 109(2), 493–498.

the arc between α_n and α_m divided by its tangential velocity $v_{p,x}$:

$$t_s = \int_{\alpha_n}^{\alpha_m} \frac{\pi(d_b + d_p)}{v_{p,x}} d\alpha \quad [49]$$

This gives a sliding contact time in terms of an average $v_{p,x}$ which is computed using an average vorticity $\zeta_{s,avr}$ and an average value for $\sin \alpha$, with α in degrees:

$$t_s = \frac{(\alpha_m - \alpha_n)}{360} \times \frac{\pi(d_b + d_p)}{\bar{v}_{p,x}} \quad [50]$$

Figure 9 shows sliding times computed for a 160 μm particle, of density $\rho_p = 2.5 \text{ g cm}^{-3}$ with a terminal settling velocity $v_T = 1.58 \text{ cm s}^{-1}$, on 3 mm bubbles rising at $v_b = 8.42 \text{ cm s}^{-1}$ giving an approach velocity of 10 cm s^{-1} . These times show a linear dependency on the angle of contact decreasing from 40 ms at $\alpha_n = 20^\circ$ to 0 when $\alpha_n = \alpha_m = 90^\circ$.

Thinning of the Water Film Attachment

Induction time–critical thickness Li, Fitzpatrick and Slattery have developed a mathematical model from which the attachment between the bubble and the particle can be characterized. The model relates to an initially spherical bubble approaching a stationary spherical particle. As the bubble–particle separation reduces, the water film separating them will thin and possibly reach a *critical thickness* at which it will rupture.

The *induction time* is the time between the initial contact, defined by the formation of a dimple on the bubble surface, and the final rupture of the separating film. Restating the previous sentence, a condition for attachment is for the *induction time* to be shorter than the *contact time*.

The model is defined in axisymmetric cylindrical coordinates with the z -axis coinciding with the line of approach of the bubble and particle centres. The particle is assumed to be spherical of radius R_p and the bubble away from the neighbourhood of close approach is also to be assumed spherical with a radius R_b . The origin of the system is taken as the centre of the spherical particle, the frame of reference being stationary with reference to the particle.

Figure 10 shows the bubble–film interface $z = h_1(r, t)$ and the surface of the solid $z = h_2(r)$. The surface of the bubble is dimpled on the nearest point of approach to the particle on the line of centres, the rim of the dimple is located at a radius $R(t)$ from the line of centres.

It has been assumed that the initial time of the bubble–particle contact $t = 0$ occurs when the thinning rate in the film becomes dependent on radial position.

The film thickness between the two surfaces $h_x(r, t)$ is given by the difference:

$$\begin{aligned} h_x(r, t) &= h_1(r, t) - h_2(r) \\ h_0 &= h_x(r, 0) \quad \text{and} \quad R_0 = R(0) \end{aligned} \quad [51]$$

For the spherical solid particle:

$$h_2(r) = (R_p^2 - r^2)^{1/2} \quad [52]$$

Figure 10 Thin liquid film formed as a small bubble approaches a small solid particle. Reproduced with permission from Li, Fitzpatrick and Slattery (1990) Rate of collection of particles by flotation. *Industrial Engineering Chemistry Research* 29, 955–957.

The thinning of the film is due to the pressure in the film $P(r, t)$ being greater than the hydraulic pressure p_b remote from the line of centres; at this point $r = R_b$. The pressure inside the bubble p_0 is linked to the hydraulic pressure p_b by:

$$p_b = p_0 - 2 \frac{\gamma}{R_b} \quad [53]$$

Components of the thinning pressure in the film

The local total film pressure $P(r, t)$ has three components: (a) the London–van der Waals interactive pressure π_v , (b) the electrostatic π_{el} pressure due to the charges on the solid and the bubble surfaces, and (c) a pressure π_{cap} caused by the deformation of the bubble surface from that of a sphere to $z = h_1(r, t)$, in the neighbourhood of the solid particle.

For the van der Waals component, π_v , for a film of thickness h_x the following is considered:

$$\pi_v = \frac{B}{h_x^m} \quad [54]$$

When the film thickness was greater than 400 Å, $m = 4$ and $B = 10^{-19}$ erg cm, but when the film thickness was less than 120 Å the corresponding values were taken as $m = 3$ and $B = 10^{-14}$ erg.

These values are consistent with those quoted earlier for the Hamaker constant A . When B is positive the London–van der Waals forces between liquid–gas and the solid–liquid interfaces are mutually attractive.

The electrostatic interaction potential π_{el} between the particle–water and the water–bubble surfaces is given by:

$$\pi_{el} = \Delta \exp(-\kappa h_x) \quad [55]$$

where:

$$\kappa^2 = \frac{8\pi n z_i^2 e^2}{DkT}$$

$$\Delta = 64nkT \tanh\left[\frac{z_i e \psi_{s-w}}{4kT}\right] \tanh\left[\frac{z_i e \psi_{w-g}}{4kT}\right]$$

where ψ_{s-w} and ψ_{w-g} are the electrostatic potentials at the bounding interfaces. When the interfaces have the same sign, Δ is positive and the surfaces are mutually repulsive and when the signs are different, Δ is negative and the surfaces are mutually attractive.

As deformation of the bubble surface occurs, the capillary pressure in the film $\pi_{cap}(r, t)$ is a function of

the mean curvature H_1 and the bubble pressure:

$$\pi_{\text{cap}}(r, t) = p_0 - 2H_1\gamma \quad [56]$$

where γ is the surface tension of the distorted film:

$$\pi_{\text{cap}}(r, t) = p_0 - \frac{\gamma}{r} \frac{\partial}{\partial r} r \frac{\partial z_1(r, t)}{\partial r}$$

A lateral pressure gradient will develop in the water film normal to the separation distance h_x . Under this pressure gradient water will move to the bulk liquid, causing thinning:

$$\frac{\partial P(r, t)}{\partial r} = \frac{\partial}{\partial r} \left(\frac{B}{h^m} - \Delta e^{-\kappa h} - 2\gamma H_1 \right) \quad [57]$$

assuming that the van der Waals and the electrostatic disjoining pressures are attractive. To calculate the induction time it is necessary to obtain values for the velocity components of the water in the flowing film $v_r(r, z, t)$ and $v_z(r, z, t)$ in terms of the pressure gradient. For an incompressible Newtonian fluid with constant viscosity, the momentum balance equation for creeping flow for radial symmetry $v_\theta = 0$ and for negligible pressure variation in the z -direction reduces to:

$$\frac{\partial P}{\partial r} = \mu \frac{\partial^2 v_r}{\partial z^2} \quad [58]$$

A solution for $v_r(z, r)$ at time t is obtained for both a mobile and an immobile bubble–water interface:

$$v_r(r, z) = \frac{1}{\mu} \frac{\partial P}{\partial r} \left[\frac{(z - h_2)^2}{2} - \frac{h}{n} (z - h_2) \right] \quad [59]$$

where $n = 1$ for a mobile interface and $n = 2$ for an immobile interface. This, when substituted into the equation of continuity gives v_z , which together with v_r , gives a solution for the configuration of the bubble–water interface $z = h_1(r, t)t$. From this the change in film thickness at radial position r , with time follows:

$$\frac{\partial h_x}{\partial t} = \frac{1}{\mu} \frac{3-n}{2n} \left[\frac{1}{3} h_x^3 \left(\frac{\partial^2 P}{\partial r^2} + \frac{1}{r} \frac{\partial P}{\partial r} \right) + h_x^2 \frac{\partial h_x}{\partial r} \frac{\partial P}{\partial r} \right] \quad [60]$$

A radial position R_b is estimated, as the smallest value of R where the local bubble curvature is the same as that of the undeformed bubble. The force

acting on the water film at the particles surface is then computed to be:

$$F(t) = 2\pi \int_0^{R_b(t)} (P(r, t) - p_0) dr \quad [61]$$

The induction time is that when $F(t_{\text{ind}})$ is deemed just to have exceeded the adhesion energy of the solid–water interface. For the case where the effects of the electrostatic double layer can be neglected, the numerical integration shows an inverse power dependence of the induction time on the van der Waals parameter.

These conclusions have been tested against the experimental data reported by Ye and Miller whose observations were based on forcing a bubble through a solution on to a bed of particles for a predetermined time and recording as the induction time the time at which 50% of the events resulted in attachment.

The theoretical treatment predicts that when the particle radius R_p is very much smaller than the bubble radius R_b , $\log t_{\text{ind}}$ will be a linear function of $\log R_p$. This is consistent with the experimental data of Ye and Miller, although the predicted slopes are slightly lower than those reported.

When the electrostatic effects are allowed for the predictions have to be graphical as a general equation cannot be derived; there are also no experimental data available for checking. From **Figure 11** and **Table 3** it is, however, clear that these electrostatic effects are very significant.

Li, Fitzpatrick and Slattery have reported values for Δ and κ reproduced here as Table 3 which they used in conjunction with their derived relationships.

The data in the table are given for univalent ions and the surface potentials are given as equal on each surface, but both cases can be easily adapted. When the sign of the surface charges are opposite and the surfaces are consequently mutually attractive, Δ is negative.

The authors report induction times for a system corresponding to that of Ye and Miller although no direct comparisons with experimental data could be made. Figure 11 is typical of the predictions made.

For electrostatic interactive forces on a 100 μm particle in a 10^{-3} molar solution the induction times vary from 10 ms for $\pi_{el} = -80$ mV to more than a second for $\pi_{el} > +20$ mV.

As the solution molarity falls to 10^{-4} mV the induction time for $\pi_{el} = -80$ mV remains at 10 ms but falls to 100 ms for $\pi_{el} = +20$ mV.

The effect of particle size is also interesting; for a 10^{-3} molar solution and $\pi_{el} = -80$ mV the induction time is less than 1 ms for a 10 μm particle rising

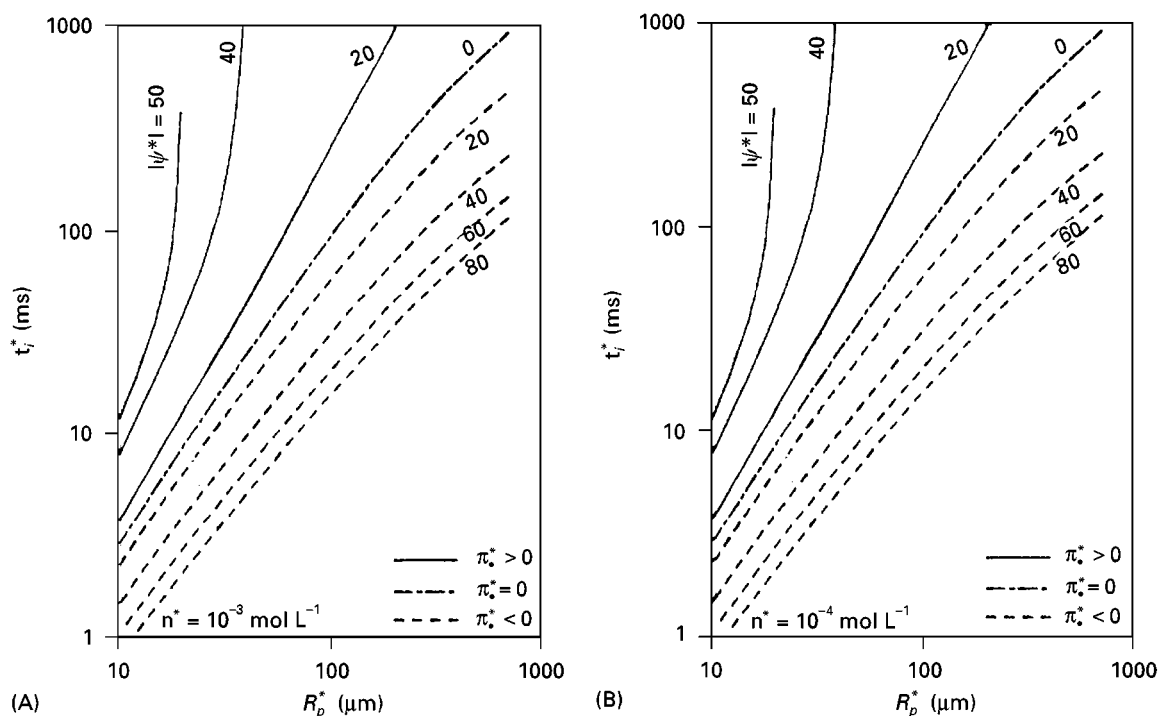

Figure 11 Induction times as a function of the charge density on particle and bubble surfaces, which are assumed equal but of similar or opposite signs, and the particle radius. (A) $n = 10^{-3}$ and (B) $n = 10^{-4}$ mol L $^{-1}$. Reproduced with permission from Li, Fitzpatrick and Slaterry (1990) Rate of collection of particles by flotation. *Industrial Engineering Chemistry Research* 29, 955–957.

to 100 ms for a 1000 μm particle. The effect of a reduction in solution molarity to 10^{-4} does not, however, change the induction times significantly as it does in the previous case.

Although the model refers only to single bubble–single particle contact and the experimental data are similarly idealized, it is nevertheless valuable

as it predicts induction times in fundamental terms which surely provides a sound basis for the experimental use of them as a characterizing parameter, for the development of reagent addition strategies for industrial separations.

Transfer across the Pulp–Froth Interface

The bubble structure at the top of the pulp is shown for two-phase foams in **Figure 12**. It can be shown that the rate at which bubbles are required to cross through a volume at the top of the pulp, described by the surface area of the cell multiplied by one bubble diameter, is determined by the overall aeration rate to the cell and the bubble size produced by the agitator or sparger.

The free rise velocity of a single bubble of a typical size produced in this way has a residence time significantly smaller than that calculated by dividing the liquid volume in the cell by the aeration rate. The dispersed bubble hold-up in the pulp is thus considerably less than that the bubble hold-up in the close-packed foam structure, producing a sharp discontinuity in the bubble volumetric fraction at the pulp–froth interface.

If, at the bottom of the foam layer the bubbles remain spherical in a closest-packed rhombohedral

Figure 12 The structure of the interface between bubbles dispersed in water containing surfactant and the froth. No particles are present in this system.

structure, the volume fraction occupied by inter-bubble water will be $\varepsilon = 0.26$.

This means that solids transfer from the pulp to the froth in two ways. In the first the valuable particles are selectively attached to the bubble surface, while in the second the particles will be non-selectively entrained in the inter-bubble water. This entrainment will adversely affect the selectivity of the separation, but will apparently improve the total particle recovery.

Froth Microprocesses

Grade Enhancing – General

For the froth to perform a grade-enhancing (cleaning) function it is clearly necessary to reduce the entrainment of undesired solids.

The froth which forms at the pulp–froth interface is a close-packed structure of spherical bubbles (*kugelschaum*), which it will have a volumetric water fraction of about 30%. The solids content of this water will not have been selectively separated. To reduce the amount of entrained solids at the froth overflow it is necessary either to reduce the water content by drainage or to displace the solids in the inter-bubble water by adding external wash water at the upper froth surface.

Removal of Entrained Solids

Coalescence Froths with high water contents are mobile and overflow at high rates giving good recoveries at the expense of low grades. These froths occur when the bubbles on their upward passage from the pulp–froth interface through the froth to the overflow, retain their shape and do not coalesce.

It is theoretically possible that selective drainage of solids within the entrained water may occur, giving some grade improvements without a reduction in water content. However, the settling path within the froth is down the plateau borders and even with heavy minerals and low-density gangue, the differential settling rates are usually small and significant upgrading from this effect is uncommon.

The volume fraction of water in the *kugelschaum* can be reduced by allowing the close-packed spherical bubbles to coalesce to form a polyhedral structure (*polyederschaum*). The lower water content of this structure is related to the thinness of the water lamellae separating the flat polygonal sides of the bubbles.

The point at which three bubbles meet is called a plateau border. Drainage occurs down a network of these borders. At the plateau border the curvature of the bubble surfaces is relatively high. The difference between the curvature of the bubble surfaces at the plateau border and that of the flat sides, generates a capillary pressure which causes the lamellar water to flow towards the plateau border. This causes them to thin further to a point where they may rupture causing further coalescence.

The reduction of the froth water content by drainage is directly dependent on the degree of bubble coalescence which occurs during their passage upwards through the froth. This in turn depends on the stability of the inter-bubble lamellae of the *polyederschaum*.

The coalescence may possibly cause some rejection of the valuable solids into the draining inter-bubble water, and may also be associated with an increased bursting rate of the froth bubbles, which will also cause valuable solids to be rejected into the drainage water.

This suggests a linkage between the appearance of the overflowing froth and the cell performance. Regulation of the degree of coalescence which occurs in the froth is achieved by varying the addition of the frother. Woodburn, Austin and Stockton have reported experimental studies, carried out in a 1 litre laboratory Denver cell, relating to the removal of ash-forming mineral from a low-rank British coal. In these the demineralized coal is the valuable product and the ash-forming mineral the waste product. The tests relate on-line visual images to cell performance as characterized by grade-recovery curves

Figure 13 Grade recovery trajectories of batch coal flotation tests with varying initial single additions of the anionic collector/frother sodium dodecyl sulfate. Reproduced with permission from Woodburn ET, Austin LG and Stockton JB (1994) A froth based flotation kinetic model. *Chemical Engineering Research and Design* 72(A2), 211–226.

(Figure 13). There is a limiting achievable grade which reflects perfect separation. This is because, that even after fine grinding there is a residual inherent mineral content of the fine coal. This material which is determined in this case, by the ash content of the float fraction in a heavy medium (specific gravity of 1.4) centrifugal separation, is referred to as being unliberated.

Figure 13 shows a progressive reduction of grade with increasing recovery for a single test, and an overall grade reduction and recovery increase over all the tests, with increased addition of the frother/collector sodium dodecyl sulfate (SDS).

Each grade–recovery curve, with the partial exception of the run with 0.10 mM SDS initial addition, completely encloses all runs with higher initial additions. This run was done on a different coal sample from the same pit. Tables 4–7 show that for the coal froths the average concentration of SDS in the concentrate increases as expected with increases in the initial dose, but does not change significantly over a run despite the observed increased coalescence.

In all the tests the concentrate was free-flowing and then terminated when the froth would no longer flow, and had a high bubble bursting rate. Both effects are consistent with lamellae thinning to below a thickness where lateral flow to the plateau border stops. The reduction of grade with time and increased coalescence, during the course of a single test, is however not consistent with the simple entrainment model.

A possible explanation for the grade reduction despite the increased coalescence, is that there may be a competitive adsorption of valuable and waste material on the bubble surface rather than perfect selectivity. As a batch test proceeds there is an increasing fraction of waste solids in the pulp, which may consequently cause a corresponding increase in the waste solid attachment to the bubble surface. The increasing waste solid concentration may also contribute to the decreased lamella stability, despite the presence of SDS, because of the lower repulsion between two closely adjacent bubble surfaces, rather than that between the two surfaces with a higher fraction of coal. These observations must be treated as speculative.

Figure 14 shows for the same series of tests the percentage of solids in the overflowing concentrates as a function of time. From this it can be seen that the water content of the concentrate increases with increased SDS addition. Comparison with the grade–recovery curves of Figure 13 clearly relates decreases in grade and increase in recovery with the concentrate water content. It is also interesting to note that the time of a single test increased with increased surfactant reflecting the increased stability of the bubbles in the froth. For the run with 0.2 mM initial SDS addition, the solids content in the overflowing froth towards the end of the run was about that of the pulp solids, which indicates almost complete entrainment.

Figures 15 and 16 show the appearance of the top surface of the froth for the runs with initial SDS additions of 0.04 and 0.05 mM L⁻¹, respectively.

Tailings	6.63	–	63.0	–	4.74	34.5

Feed mass 49.5 g coal, feed ash 12.7%, total water 850.6 g, sodium dodecyl sulfate 0.04 mM. Reproduced with permission from Stockton J (1989) PhD thesis, UMIST, Manchester.

Table 4 reports for the 0.04 mM run, an increase in the mean bubble size from 3.07 mm at 17 s to 4.67 mm at 62 s, while for the 0.05 mM run the mean bubble size varied from 1.7 mm at 23 s to 3.6 mm at 77 s.

The smaller bubbles of the 0.05 mM run corresponded with poorer grades and lower concentrate solids content than those observed in the 0.04 mM run. It can be seen that in both runs the mean bubble size as viewed from above increased with time of the test.

Figure 17 shows the junction of three bubbles after coalescence. The plateau border can be seen, as can be the plane liquid lamella separating two adjacent bubbles. The presence of solids on the bubble surfaces can also be seen. These show incomplete surface coverage.

Displacement washing The structure of a column flotation cell is quite different from that of the mechanical (sub-aeration) cells which have by implication formed the basis of this presentation. In both, air bubbles are dispersed through a suspension of solids in water, but while in mechanical cell this is done with an aerating agitator, in column cells air is disper-

sed from the bottom of the pulp through a sparger. In mechanical cells the aspect ratio is such that the cross-section is of the same order as the height of the cell while in column cells the depth of the collection/bubbling zone (pulp) is much greater than the cross-section. For instance Yianatos, Finch and Laplante quote for the molybdenum column cleaner and recleaner cells, at the Noranda Mines, Gaspé in Quebec, cross-sections which are respectively 0.91 and 0.47 m square with overall heights of 12 m for both.

In the column cell the feed suspension is added near the top of the bubbling zone and the particles are free to settle. While they are settling they encounter the rising bubbles in a physical situation which is closer to that envisaged in the model of Flint and Howarth, than that in the strongly turbulent mechanical cells. The flow pattern of the rising gas bubbles and the settling solids approximates to plug flow whereas that in the mechanical cells is closer to perfectly mixed.

As with the subaeration/mechanical cells a froth phase forms above the aerated pulp/collection zone into which entrainment of water containing non-selectively separated solids occurs. In column cells, the inter-bubble water containing the unwanted

solids is displaced by spraying solids-free wash water on to the upper froth surface.

Yianatos, Finch and Laplante reported laboratory and plant studies relating to the effectiveness of the displacement washing. For the plant tests these involved a broad step pulse injection of 200–600 g of LiCl tracer dissolved in 5 L of water into the feedbox. The feedbox was 35 cm below the collection zone/froth interface. Tracer concentrations were measured 100 cm below the injection point, 10 cm into the froth above the interface, from the overflowing concentrate at the top of the froth and from the tailings stream at the base of the cell.

In the 0.91 m² cross-section cell, a froth zone varying between 45 and 130 cm depth was reported while in the 0.45 m² cross-section cell the froth depth varied between 110 and 140 cm.

For all the runs reported virtually no tracer was detected in the overflowing concentrate, although at

high superficial gas rates of 2 cm s⁻¹ tracer was detected in the froth up to 70 cm above the interface. The tracer residence time distributions (RTD) after the pulse injection, at 35 cm below the froth interface, indicated significant mixing in the water between the

feed point and the froth interface. Similarly, the tracer RTDs in the tailings stream showed significant axial mixing in the collection zone below the feed point.

Figure 17 Image of the upper surface of coal-laden bubbles. Note the inter-bubble lamellae and plateau border.

For both cells the mean residence time of the tracer in the collection zone was approximately 10.0 min.

From these tests it seems that froth depths up to 100 cm may be needed to ensure complete removal of entrained solids from the final concentrate. These tracer studies are consistent with the high grades which are achieved in these cells.

There is a question relating to the capacity of column cells. The rate of flotation in both types of cell depends on the effectiveness of the bubble–particle collision and attachment processes. A key factor in the evaluation of these is the velocity of approach of the particle and the bubble. In the mechanical cells high approach velocities are achieved through the turbulence in the pulp. In column cells the approach velocity is determined by the bubble rise and particle settling velocities. For small particles, and hence small bubbles, these velocities are so low, that the collection zone must be impractically high if the necessary frequency of bubble–particle encounters is to be achieved. In industrial practice the column cells are most effective where high grades at low throughputs are required. This is particularly the case where previously produced concentrates have to be cleaned and re-cleaned.

Sam, Gomez and Finch have shown that the bubble rise velocity is reduced in the presence of surfactants over that in distilled water and further that the surfactant adsorption is a rate process. This retardation of the rising bubble appears to be a function of the surface immobility which in turn should improve attachment after a successful interception, by increasing the contact time with individual particles.

Tuteja, Spottiswood and Misra in reporting the reverse flotation of undesired talc from a gold-bearing pyrite ore, have shown that there is virtually no grade change with height in the collection zone but that there is a dramatic increase in the percentage of talc in the froth solids, increasing from 3% at the base of the froth to 50% at the concentrate overflow. At the same time the presence of an arsenic contaminant fell from 3750 ppm in the pulp solids to 750 ppm in the concentrate overflow.

Cell Design and Control

Outline of the Factors Influencing Single Cell Design

In general, the contractor is responsible for the engineering design of the cell, while the customer is responsible for the design of the separation system. This involves the selection of both chemical collectors, depressants and frothers and also the solution pH. The principles underlying these have been thoroughly discussed earlier.

In addition, the degree of pretreatment required to liberate the desired component from the waste, prior to the flotation separation, has to be decided. Obviously the two parties to the project have to interact and this is done in the first instance through laboratory and pilot plant trials, followed if possible by a large-scale plant trial.

The contractor's responsibility is to provide, within economic constraints, equipment in which dispersed bubbles of a specified size will be generated in the pulp, to achieve efficient bubble interception with particles of a specified density and size distribution. The fundamental considerations underlying this have been discussed earlier. There are two main types of equipment, which employ very different techniques for bubble-particle contact.

Mechanical sub-aeration cells In these cells the pulp is stirred vigorously by a centrally located agitator, on of whose functions is simply to prevent solids settling. In most cells the central agitator also induces air down an annulus surrounding its shaft and disperses the air radially as bubbles into the pulp. The intense turbulence generated by the agitator favours a high rate of bubble-particle collision, but also if the turbulent intensity is too high then previously attached particles may detach from the bubble surface.

The flow pattern in these cells divides into an intense inner region in the vicinity of the impeller, and a much larger less turbulent outer region in the bulk of the cell. In the relatively quiescent outer region the bubble-particle aggregates rise to form a froth. The cell design provides a sufficient depth between the pulp/froth interface and the overflow weir to permit drainage of some entrained solids. In commercial cells the froth can be removed by mechanical scrapers so froth mobility at the overflow is not usually a serious concern.

Finally, a class of cells should be mentioned in which specific attention is paid to achieving a high degree of bubble-particle contact without subsequent detachment. One example of this class of intensive cell, pumps the feed through a venturi nozzle which induces air under pressure into the low pressure region at the venturi throat. This causes bubbles to form which appear to nucleate on the solid particles.

Column cells In these cells particle-bubble interception occurs under low turbulent conditions essentially through particles settling under gravity meeting rising bubbles. The bubbles are introduced at the bottom of the collection zone through a sparger, and the feed particle suspension near the top of the collection zone. The low approach velocities of fine particles

settling slowly and bubbles rising against down-flowing water reduce the interception rates, thus requiring more possible contacting opportunities, leading to very deep collection zones.

At the top of the collection zone a froth bed forms, which itself may be deep with bed depths of over 1 m being reported. The column cells produce very high purity products, achieved largely by the displacement of entrained water after adding wash water to the upper froth surface.

Multiple Cell Circuits

Circuit configuration In industrial operation it is necessary to have many cells in operation if the desired upgrading of large quantities of low-grade feed is required. The cells are operated in banks in which the tailings stream from one cell moves in sequence to the next. However, the concentrates are withdrawn from each individual cell into a concentrate launder which runs parallel to the cell bank.

Each bank then produces a single concentrate and a single tailings stream. These streams may in their turn be reprocessed. Typically, the first bank in a circuit would be called the rougher. The tailings stream from the rougher is then fed to the scavenger bank whose function is to recover any residual valuable material which may not have been floated in the rougher.

The concentrate stream from the rougher is fed to the cleaner bank whose function is to improve its grade. Finally, it may be necessary further to upgrade the cleaner concentrate by sending it to a recleaner bank. The circuit is completed by internal recycling. The final product of the circuit is the cleaner (recleaner) concentrate and the scavenger tailings.

The chemical environment of a particular bank of cells is determined by the addition of chemicals and pH regulators to the feedbox of the first cell of the bank.

Kinetic modelling For the design of circuits, a description of the kinetics of particle removal of any given cell to the concentrate overflow is required. Attempts to develop such a model have centred on the transfer rate in terms of the local concentration of a solid class in the pulp. This requires a matrix of deterministic single rate constants characterizing each solid species and particle size class within that species. These parameters can be determined either from batch cell tests or from the performance of a single continuously operating cell. Even with a large dimension matrix of rate constants, the ability of the model to predict accurately circuit performances of operating plant, is limited. The fundamental weakness of this approach is that it treats the pulp and the froth as

one, ignoring the very different subprocesses affecting separation in each of the phases.

On-line control The difficulty of implementing on-line control is the necessity for off-line analysis of solid grades and to a certain extent off-line measurements of the mass flow of solids and water at different points in the circuit.

Informal operational control is performed by experienced operators following subjective comparisons of the appearance of overflowing froths, with a desired structure. The advantage of this approach is that the structure of the overflowing froth is easily observable and corrective actions can be rapidly implemented.

Currently several groups of academic workers are working on quantifying the froth characterization using on-line image analysis, with promising results. This is, of course, only a first step in the development of a feedback control system by which optimum operation can be effected.

This is an exciting development which can be anticipated with some confidence to lead to implement optimal control strategies.

ION EXCHANGE

A. Dyer, University of Salford, Salford, UK

Copyright © 2000 Academic Press

Introduction

Ion exchange has been described as the oldest scientific phenomenon known to humanity. This claim arises from descriptions that occur in the Bible and in the writings of Aristotle, but the first truly scientific allusion to ion exchange is attributed to two English agricultural chemists in 1850. These were J. T. Way and H. S. Thompson, who independently observed the replacement of calcium in soils by ammonium ions. This discovery was the precursor to the study of inorganic materials capable of 'base' exchange, and in 1858 C. H. Eichorn showed that natural zeolite minerals (chabazite and natrolite) could reversibly exchange

cations. The importance of this property in water softening was recognized by H. Gans who, at the turn of the century, patented a series of synthetic amorphous aluminosilicates for this purpose. He called them 'permutites', and they were widely used to soften industrial and domestic water supplies until recent times, as well as being employed in nuclear waste treatment. Permutites had low ion exchange capacities and were both chemically and mechanically unstable.

This early work has generated some myths commonly stated in elementary texts, namely that zeolite minerals are responsible for the 'base' exchange in soils and that permutites are synthetic zeolites. The presence of clay minerals in soils accounts for the majority of their exchange capacity, and zeolites by definition must be crystalline. Both these topics will arise later in this article.

The emphasis started to change in the 1930s when the Permutit Company marketed organic ion exchange materials based on sulfonated coals, which had been known from about 1900. These were sold as 'Zeo-Karb' exchangers and, despite their low capacities and instability, were still available in the 1970s.

Ion exchanger production was radically altered by the discovery of synthetic resin exchangers by B. A. Adams and E. L. Holmes in 1935. They used a condensation polymerization reaction to create a granular material able to be used in columns and until very recently the majority of ion exchange has been carried out on resin-based materials. Sophisticated developments of novel resin exchangers (and inorganic materials), together with improvements in properties of commercial products, continue to be heightened by the extensive area that modern ion exchange interests cover. The process governs ion separations important to analytical techniques, large-scale industrial water purification, pharmaceutical production, protein chemistry, wastewater treatment (including nuclear waste) and metals recovery (hydrometallurgy). In addition it has a critical role in life processes, soil chemistry, sugar refining, catalysis and in membrane technology.

This article will attempt a modern overview of inorganic and organic ion exchange materials, including their properties and the development of new substrates. It will consider the theory of ion exchange together with its industrial and analytical importance. Its wider role in the other aspects mentioned above will also be briefly discussed.

What Is Ion Exchange?

Some Definitions

A broad definition of ion exchange is that it is the transfer of ions across a boundary; this would then cover movement of ions from one liquid phase to another. This is too broad a base for the purpose of this article, which will restrict itself to those exchanges of ions that occur between a liquid phase and a solid (organic or inorganic) that is insoluble in that liquid. A simple representation of the process when univalent cations are being transferred is given in the chemical equation [1] below:

Here $M^-A_c^+$ represents a solid carrying a negative charge ('solid anion', sometimes described as a 'fixed ion') neutralized by the A^+ ions inside its structure. The A^+ ions are replaced by B^+ originally in the solution phase (normally aqueous). The subscripts 'c' and 's' refer to the solid and solution phase, respec-

tively. The process must be totally reversible to fit the strict definition of ion exchange. However, in practice interference from other nonreversible events may occur. Examples of disruptive influences that may have to be faced are the imbibition of salt molecules, precipitation reactions, chelating effects, phase changes and surface sorption. Some of these will be mentioned later.

An equivalent stoichiometric equation can be written for the anion exchange process, as in eqn [2]:

Now M carries a positive charge ('solid cation' or 'fixed ion') and X and Y are exchanging anions moving reversibly between solid and liquid phases. The ion pairs, A , B and X , Y are called 'counterions'. An ion which is mobile and has the same charge as that of the solid exchanger is called a 'co-ion'.

The extent to which an exchanger can take up ions is called its 'capacity'. In the case of an organic resin exchanger, this can be related to the number of fixed groupings that have been introduced into the polymer as part of its synthesis to create ion exchange properties. These are known as 'ionogenic' groups and are either ionized, or capable of dissociation into fixed ions and mobile counterions. In an inorganic exchanger the ionogenic nature of the solid matrix arises from the presence of positive or negative charges on the solid (usually on an oxygen ion). These charges are a consequence of metal cations in the exchanger that are in nonexchangeable sites. Examples of these will be discussed later.

Recent workshops on ion exchange nomenclature have suggested that the ion exchange capacity is expressed as the concentration of ionizable (ionogenic) groups, or exchange sites of unit charge, per gram of dry exchanger. The units of concentration should be millimoles or milliequivalents per gram. This definition can be taken as the theoretical capacity – Q_0 .

The workshops also prefer the term 'loading' to describe the capacity experienced under the specific experimental conditions at which the ion uptake is being observed. This can be higher or lower than the theoretical capacity. Higher capacities can arise from electrolyte imbibition or surface precipitation, and lower capacities often arise in inorganic exchangers when all the sites of unit charge are not accessible to the ingoing ion. These circumstances will be considered later.

The suggested definition of loading is the total amount of ions taken up per unit mass, or unit volume, of the exchanger under clearly defined experimental conditions. The concentrations again should be given in millimoles or milliequivalents, but with

the option to relate this to mass *or* volume. An appropriate symbol would be Q_L .

It should be noted that this is a new approach, differing from the IUPAC recommendations of 1972, and is felt necessary because of the new interest in inorganic exchangers whose properties do not fit the IUPAC concepts.

The definition of capacity associated with column use remains unchanged. The 'breakthrough capacity' (Q_B) of a column is still best defined according to the IUPAC definition as the practical capacity of an ion exchanger bed under specified experimental conditions. It can be estimated by passing a solution containing the ion to be taken up through the column and observing the first appearance of that ion in the column (bed) effluent, or when its concentration in the effluent reaches a convenient, arbitrarily defined, value. Q_B can be expressed in units of millimoles, or milliequivalents, of wet, or dry, exchanger using volumes or mass as appropriate.

General Properties of Exchange Media

An ideal ion exchange medium is one that fulfils the following criteria:

1. a regular and reproducible composition and structure;
2. high exchange capacity;
3. a rapid rate of exchange (i.e. an open porous structure);
4. chemical and thermal stability and resistance to 'poisoning' as well as radiation stability when used in the nuclear industry;
5. mechanical strength stability and attrition resistance;
6. consistency in particle size, and compatibility with the demands of the use of large columns in industry.

In addition some applications demand the ability to exchange a specific ion(s) selectively from high concentrations of other ions. This is particularly true for aqueous nuclear waste treatment and in hydrometallurgy. In some of these applications ion exchangers with lower capacities can be effective.

The Theory of Ion Exchange

Ion Exchange Equilibria

When an ion exchange solid is allowed to reach equilibrium (checked by a prior kinetic experiment) with a solution containing two counterions, generally one ion will be taken up preferentially into the solid. The solid is then said to be exhibiting *selectivity* for the preferred ion. Selectivity can be quantified by the experimental construction of an ion exchange iso-

therm. At a fixed temperature solutions containing counterions A and B in varying proportions are allowed to equilibrate with known, equal, weights of exchanger in, say, the MA form. The total ionic concentration of the ions A and B in the respective solutions is kept constant, i.e. each solution has the same normality (N) but, as the concentration of B increases it is compensated by a decrease in concentration of A. At equilibrium the solids and liquids are separated and *both* phases analysed for A and B.

This enables an isotherm to be plotted that records the equilibrium distributions of one of the ions between the two phases. Examples of typical isotherms are shown in Figure 1. The selectivity shown by an isotherm can be quantified; a general example of cation exchange will be used to illustrate this. First eqn [1] will be rewritten for an exchange involving cations (A, B) of any charge, as in eqn [3]:

where $Z_{A,B}$ are the valences of the ions and the bar represents the ions inside the solid phase.

The axes of the isotherm record the equivalent fraction of the ingoing cation (A) in solution (A_s) against its equivalent fraction in the exchanger (A_z). These quantities are defined in eqns [4] and [5] below:

$$A_s = Z_A m_A / (Z_A m_A + Z_B m_B) \quad [4]$$

and:

$$\bar{A}_z = Z_A M_A / (Z_A M_A + Z_B M_B) \quad [5]$$

Figure 1 Idealized ion exchange isotherms (see text for details).

where $m_{A,B}$ and $M_{A,B}$ are the ion concentrations in mol dm^{-3} in solution and solid, respectively.

On Figure 1 the dashed line shows the case where the solid has an equal selectivity for ions A and B. The isotherm (3) describes the circumstance when A is selectively taken up, while isotherm (2) describes the circumstances when B is favoured by the exchanger.

A simple quantitative expression of the selectivity is via the selectivity factor (α) defined in eqn [6]:

$$\alpha = \bar{A}_C m_B / \bar{B}_C m_A \quad [6]$$

where by definition:

$$\bar{B}_C = 1 - \bar{A}_C \quad [7]$$

In Figure 1 α can be calculated from area (a) divided by area (b), illustrated for a typical isotherm (1).

Not all isotherms in the literature are constructed in the formal way described above. Often they arise from solutions containing only the ingoing ion placed in contact with the exchanger, only one ion is analysed in one phase, and various units of concentration are used. These simple approaches are still valid comparisons of *practical* selectivities, but when isotherms are needed to generate thermodynamic data the more rigorous experimental methodology must be followed. It is also necessary to demonstrate that the exchange being studied is fully reversible to allow the laws of mass action to be applied. When inorganic exchangers are involved it may be appropriate not to dry the solid before the reverse leg of the isotherm is constructed, as heating the solid can change the number of cation sites partaking in the exchange. This is particularly so for the zeolite minerals. In cases where organic resin exchangers are examined, the resin is used preswollen (fully hydrated) to avoid discrepancies caused by the resin expanding on initial contact with the solution phase.

Distribution Coefficients

Each point on an isotherm (simply or rigorously constructed) represents the distribution of ions between the solid and liquid phases. At each point a *distribution coefficient* (D_A) can be defined for the ion A as follows. D_A = concentration of A per unit weight of dry exchanger/concentration of A per unit volume of external solution.

The distribution coefficient is widely used as a convenient check of selectivity at fixed, pre-determined, experimental parameters. Equilibrium must have been achieved for this assessment to be valid.

Analysis of Isotherms to Provide Thermodynamic Data

For a fully reversible isotherm a mass action quotient (K_m) can be used to defined the process, as with any other reversible chemical process, namely:

$$K_m = A_Z^{Z_B} m_B^{Z_A} / B_Z^{Z_A} m_A^{Z_B} \quad [8]$$

From this the thermodynamic constant (K_a) can be determined using eqn [6]:

$$K_a = K_m \Gamma (f_A^{Z_B} / f_B^{Z_A}) \quad [9]$$

where:

$$\Gamma = \gamma_B^{Z_A} / \gamma_A^{Z_B} \quad [10]$$

γ_A and γ_B are the single ion activity coefficients of A^{Z_A} and B^{Z_B} , respectively, in solution, and $f_{A,B}$ are the activity coefficients of the same ions in the solid phase.

K_a can be determined by graphical integration of a plot of $\ln K_m \Gamma$ against \bar{A}_Z (or by an analytical integration of the polynomial that gives the computed best fit to the experimental data).

The quantity $K_m \Gamma$ can be described as:

$$K_c = K_m \Gamma \quad [11]$$

where K_c is the Kielland coefficient related to K_a by the simplified Gaines and Thomas equation:

$$\ln K_a = (Z_B - Z_A) + \int_0^1 \ln K_c dA_Z \quad [12]$$

Values for $\gamma_{A,B}$ cannot be determined, but Γ is available from the mean stoichiometric activity coefficients in mixed salt solutions via eqn [10]:

$$\Gamma = \gamma_B^{Z_A} / \gamma_A^{Z_B} = ([\gamma_{\pm BX}^{(AX)}]^{Z_A(Z_B + Z_X)} / [\gamma_{\pm AX}^{(BX)}]^{Z_B(Z_A - Z_X)})^{1/Z_X} \quad [13]$$

In eqn [13], Z_X is the charge on the common anion $\gamma_{\pm BX}^{(AX)}$, and $\gamma_{\pm AX}^{(BX)}$ can be calculated from $\gamma_{\pm BX}$ and $\gamma_{\pm AX}$ using the method of Glueckauf. $f_{A,B}$ values are available from the Gibbs-Duhem equation.

Having obtained K_a , a value of ΔG^θ can be gained from:

$$\Delta G^\theta = - (RT \ln K_a) / Z_A Z_B \quad [14]$$

where R and T have their usual meanings, and ΔG^θ is the standard free energy per equivalent of charge.

The standard states of the exchanger relate to the respective homoionic forms of the exchanger immersed in an infinitely dilute solution of the corresponding ion. This implies that the water activity in the solid phase in each standard state is equal to the water

activity in the ideal solution, and that the standard states in the solution phase are defined as the hypothetical ideal, molar (mol dm^{-3}) solutions or the pure salts according to the Henry Law definition of an ideal solution.

At this point it should be commented that this approach is based on a simplified Gaines and Thomas treatment. In the complete version of eqn [12] the LHS should be $\ln K_a - \Delta$, where Δ is a water activity term. For most selectivity studies the ΔG^θ values measured using the simplified treatment are adequate.

To obtain a *selectivity series*, isotherms should be constructed for a homoionic exchanger initially in, say, sodium form in contact with solutions of ingoing ions (for instance Li, K, Rb, Cs). This yields ΔG^θ values that, when arranged in order of decreasing negativity, provide an assessment of the affinity the exchanger has for the alkali metals.

Ion Exchange Kinetics

When an exchanger is in contact with a solution of exchanging ions the rate of exchange can be rate controlled by one of three steps:

1. *film diffusion* – controlled by the rate of progress of an ion through a film of water molecules, which by virtue of the surface charge on the exchanger can be regarded as ‘stagnant’ (the Nernst layer);
2. *particle diffusion* – controlled by the progress of ions inside the exchanger;
3. *chemical reaction* – controlled by bond formation. Examples of this process are not simple to define but the most often cited case is when chelating *ionogenic* groups, present in an ion exchange organic resin, are able to form strong bonds with, say, a transition metal ion to create a very specific extractant.

The three possible steps are illustrated in **Figure 2**.

Distinction between *film* and *particle* control can be made from the following criteria.

- *Film diffusion* is affected by the speed of stirring in a batch exchange (or the rate of passage of liquid through a column of exchanger). The rate of diffusion will directly depend upon the total concentration in the external solution.
- *Particle diffusion* has a rate that is dependent on the particle size, and is independent of both stirring speed and external solution concentration.

Kressman has devised a simple *interruption* test to distinguish between *film* and *particle* control. The exchange being studied is interrupted for a short

Figure 2 Possible rate-determining steps in an ion exchange process. Step I, diffusion of ions through a surface film. Step II, diffusion through the solid exchanger. Step III, formation of chelate bond at the ionogenic group.

period of time by separating the liquid and solid phases. The phases are then recombined to recommence the exchange. Provided that the exchange is remote from equilibrium at the time of interruption, diagnostic rate profiles will ensue. The *film*-driven process will have an undisturbed profile, whereas the *particle*-driven step will have attained a partial equilibrium even in the absence of an external driving force. The different profiles observed when fractional attainments of equilibrium with time are plotted are illustrated in **Figure 3**.

Rate Equations

When diffusion is the rate-controlling step, in principle an equation can be written to elucidate experimentally derived plots of the fractional attainment of equilibrium with time for an ion exchange process. In practice this is difficult to achieve because the movement of one counterion (A) is coupled to the other (B), and this must be taken into account in both *film*- and *particle*-controlled exchange. A further complication arises in that water fluxes can play a significant part in affecting rates of exchange, especially for cations in the solid phase.

Detailed discussions on the appropriateness of the many equations available for kinetic interpretation of ion exchange results is beyond the scope of this article, and interested readers should consult the sources provided in the Further Reading section for further information.

So far as column data are concerned, the usual experiment method is to obtain a breakthrough curve, like those shown in **Figure 4**, where the appearance of the ingoing ion in the effluent is plotted against the volume of solution passed through the column. The effectiveness of the exchange can then be simply quantified in terms of the number of ‘bed-volumes’ passed through the column before the ingoing ion is detected in the effluent. This

Figure 3 The effect on the shape of the ion exchange profile caused by interrupting the time of exchange. (Reproduced from Harland, 1994, with permission.)

requires that the profile is reasonably sharp so that the breakthrough point can be estimated. The shape of the profile is a function of the selectivity; when $K_A^B \gg 1$, $\alpha_A^B \gg 1$, the exchange front is sharp, and conversely when K_A^B , $\alpha_A^B \ll 1$ the front is more ill-defined (see Figure 4).

Ion Exchange Materials

Organic Resins

These are the most widely used of exchangers. They are made by addition polymerization processes to

produce resins capable of cation and anion exchange. There is much on-going research devoted to devising synthetic routes to new resins aimed at the refinement of their capabilities, but the bulk of commercial production follows well-established routes.

Polystyrene resins Ethenylbenzene (styrene) readily forms an addition polymer with divinylbenzene (DVB) when initiated by a benzoyl peroxide catalyst. The polymerization process can be controlled to produce resins with various degrees of cross-linking as robust, spherical, beads. The ability to vary the extent of cross-linking increases the range of possible applications by altering the physical and chemical nature of the beads. In addition the production process can be moderated to give beads of closely controlled particle size distribution, a requirement for the industrial use of resins in large columns. Subsequent treatment of the styrene-DVB copolymer beads can introduce ion exchange properties. If the beads are treated with hot sulfuric acid the aromatic ring systems will become sulfonated, thereby introducing the sulfonic acid functional group ($-\text{SO}_3\text{H}$) into the resin. When the treated resins are then washed with sodium hydroxide or sodium chloride, the sodium form of the resin (R) is produced, namely:

The sodium form is used as a strong acid cation exchanger, the sodium ion being the ion for which the resin has least selectivity.

Figure 4 Breakthrough curves. (A) Favourable equilibrium, $K_A^B > 1$, shape of profile constant throughout the bed. (B) Unfavourable equilibrium, $K_A^B < 1$, edge of profile becomes more spread out with time. (Reproduced from Harland, 1994, with permission.)

Anion functionality can be introduced by a two-step process. The first step involves a chloromethylation using a Friedel–Crafts reaction between the copolymer and chloromethoxymethane with an aluminium chloride catalyst. The second step is to react the chloromethyl groups ($-\text{CH}_2\text{Cl}$), introduced into the styrene moieties, with an aliphatic amine. If this is trimethylamine, $(\text{CH}_3)_3\text{N}$, then the functional group produced on the resin is $\text{R}-\text{CH}_2\text{N}(\text{CH}_3)_3^+\text{Cl}^-$, and the resin is said to be a Type I strongly basic anion exchanger. The use of dimethylethanolamine $[(\text{CH}_3)_2(\text{C}_2\text{H}_4\text{OH})\text{N}]$ to react with the chloromethyl groups yields a resin with the functional group $\text{R}-\text{CH}_2\text{N}(\text{CH}_3)_2(\text{C}_2\text{H}_4\text{OH})^+\text{Cl}^-$, which is a Type II strong base anion exchanger. When methylamine, or dimethylamine, are used weakly basic resins are obtained, with the respective functional groups $\text{R}-\text{CH}_2\text{NH}(\text{CH}_3)$ and $\text{R}-\text{CH}_2\text{N}(\text{CH}_3)_2$.

Acrylic resins DVB forms polymers suited to ion exchange with materials other than styrene. The most commonly used are its copolymers with propenoic (acrylic) monomers. The use of methylpropenoic acid gives a weakly basic cation exchange resin ($\text{R}-\text{C}(\text{CH}_3)\text{COOH}$). Substituted propenoic acid monomers, propenenitriles (acetonitriles), and alkyl propenoates (acrylic esters) have all been used to make weakly basic resins. The acrylic matrix can also play host to anion functionality. Incorporation of dimethylaminopropylamine (DMAPA) produces a weak base resin, while the employment of a subsequent chloromethylation step converts this to a strong base functionality. Acrylic resins can be used to develop a material with simultaneous properties of a weak and strong base. These are called bifunctional anion exchangers. The equivalent bifunctional cation exchanger is not now commercially available, although products of this sort have been marketed in the past. The acrylic resins have advantageous kinetic and equilibrium properties over the styrene resins when organic ions are being exchanged.

Selective resins The resins described above have been developed as nonselective exchangers, where

the aim is to reduce the ionic content of an aqueous media to a minimum, such as is required in the ‘polishing’ of industrial boiler waters to reduce corrosion.

The flexibility offered by the skill of the synthetic organic chemist facilitates the introduction of specific groups into the polymer matrix to give the resulting exchanger the ability to take up an ion, or a group of ions, in preference to other ions. An example of this is the incorporation of the iminodiacetate group ($-\text{CH}_2\text{N}(\text{CH}_2\text{COO}^-)_2$) in a styrene-based matrix, which is then able to scavenge Fe, Ni, Cu, Co, Ca, Mg cations with the exclusion of other ions present. The iminodiacetate group is then described as a selective ionogenic group; further examples of these are given in Table 1.

Resins of this sort are continually being developed for specialist applications. The example in Table 1 of the use of a phenolic ionogenic group to pick up caesium has arisen from the nuclear industry. In this case a phenol-formaldehyde copolymer is used to meet the temperature and radiation stability needs of that industry.

The interaction between a selective ionogenic group and a cation probably will not be strictly ionic. Often there has been a deliberate intent to induce chelating effects to achieve the desired selectivity. If this has happened, then the rate-controlling step for progress of cations into the resin is likely to be the formation of a chemical bond, as mentioned earlier, rather than a diffusion process. When the cation would not be expected to form strong chelate bonds with the *ionogenic group*, such as the caesium cation mentioned above, then the nature of the rate-determining step is less clearly defined. If a thermodynamic approach to a specific exchange process is wanted these facts must be considered. Clearly a true chelating process will not be reversible and the theories of ion exchange, which are reliant on the application of reversible thermodynamics, cannot be invoked.

This introduces a grey area into the study of the uptake of ions onto a substrate supposedly capable of ion exchange. The problem often arises in the study of inorganic ion exchange materials – particularly oxides and hydroxides when uptake is pH-dependent,

Table 1 Examples of ionogenic groups and their selectivity

Matrix	Group	Selectivity
Styrene-DVB	Iminodiacetate $-\text{CH}_2-\text{N}(\text{CH}_2\text{COO}^-)_2$	Fe, Ni, Co, Cu, Ca, Mg
Styrene-DVB	Aminophosphonate $-\text{CH}_2-\text{NH}(\text{CH}_2\text{PO}_3)^{2-}$	Pb, Cu, Zn, UO_2^{2+} , Ca, Mg
Styrene-DVB	Thiol; thiocarbamide $-\text{SH}; -\text{CH}_2-\text{SC}(\text{NH})\text{NH}_2$	Pt, Pb, Au, Hg
Styrene-DVB	<i>N</i> -Methylglucamine $-\text{CH}_2\text{N}(\text{CH}_3)[(\text{CHOH})_4\text{CH}_2\text{OH}]$	B (as boric acid)
Styrene-DVB	Benzyltriethylammonium $-\text{C}_6\text{H}_4\text{N}(\text{C}_2\text{H}_5)_3^+$	NO_3^-
Phenol-formaldehyde	Phenol : phenol-methylenesulfonate $-\text{C}_6\text{H}_3(\text{OH}), -\text{C}_6\text{H}_2(\text{OH})\text{CH}_2\text{SO}_3^-$	Cs

and surface deposition of metal oxides and salts can occur. In many cases workers have found that the use of Freundlich isotherms (or similar treatments) can be successfully used to describe ion uptake.

Resin structures The traditional resins made as described above have internal structures created by the entanglement of their constituent polymer chains. The amount of entanglement can be varied by controlling the extent to which the chains are cross-linked. When water is present, the beads swell and the interior of the resin beads resembles a gel electrolyte, with the ingoing ion able to diffuse through regions of gel to reach the ionogenic groups. The ions migrate along pathways between the linked polymer chains that are close in dimension to the size of hydrated ions (cations or anions). This means that the porosity that they represent can be described as microporous. It is not visible even under a scanning electron microscope, as illustrated in **Figure 5**, and cannot be estimated by the standard methods of porosity determination, such as nitrogen BET or porosimeter measurements.

The tightly packed nature of these gel-type resins increases the chance of micropore blockage in applications where naturally occurring high molecular weight organic molecules (e.g. humic and fulvic acids) are present in water. This organic fouling was present in the earlier anion exchangers and led to the development of a new type of resin with more open internal structures. This was achieved by two routes, the sol and nonsol route.

In the sol method a solvent capable of solvating the copolymer is introduced into the polymerization pro-

cess. If the cross-linking is high (about 7–13%), pockets of solvent arise between regions of dense hydrocarbon chains. When the solvent is subsequently removed by distillation, these pockets are retained as distinct pores held by the rigidity arising from the cross-linking. In the nonsol method the organic solvent does not function as a solvent for the copolymer, but acts as a diluent causing localized regions of copolymer to form. These regions become porous when the diluent is removed.

These resins are termed macroporous, and the extent of their regions of porosity can be readily measured by porosity techniques and are visible in scanning electron micrographs (see **Figure 6**). Some literature describes them as macroreticulate because the pores they contain cover a much wider pore size distribution than the conventional International Union of Pure and Applied Chemistry (IUPAC) definition of a macroporous material. The IUPAC definition is traditionally related to inorganic materials where a macropore is one of greater than 50 nm in width. **Figure 7** illustrates the envisaged pore structure of a macroporous resin.

Macroporous resins are commercially available with acrylic and styrene skeletons, both cation and anion, carrying all types of functional groups. Their successful development has spawned two other major uses of acrylic and styrene resins that need highly porous media to function properly. These are the employment of resins as catalysts, and their use in the separation and purification of vitamins and antibiotics. Although these are of high industrial significance, they fall outside the intent of this article and will not be considered further.

Inorganic Ion Exchange Materials

Classification There are countless inorganic substances for which ion exchange properties have been claimed. Unfortunately a large number of these reports lack essential details of a reproducible synthesis, proper characterization and checks for reversibility. It is clear that many of the materials are amorphous and are often obtainable only as fine particles unsuited for column use. These pitfalls notwithstanding, there are many instances when inorganic exchangers are highly crystalline, well-characterized compounds, as well as instances when they can be made in a form appropriate for column use (even when amorphous). It also needs to be said that even a poorly defined ion exchanger may still be invaluable to scavenge toxic moieties from aqueous environments. This circumstance is valid in the treatment of aqueous nuclear waste and often drives the less rigorous studies mentioned earlier.

The traditional classification of inorganic ion exchange materials is:

- hydrous oxides
- acidic salts of polyvalent metals
- salts of heteropolyacids
- insoluble ferrocyanides
- aluminosilicates.

A more modern overview tends to blur some of these classes, but they still serve their purpose here with an addendum for the more recent materials of interest.

Hydrous oxides The compounds described in this section are 'oxides' precipitated from water. They retain OH groups on their surfaces and usually have loosely bound water molecules held in their structures. They can function either as anion exchangers, via replaceable OH^- groups, or as cation exchangers, when the OH groups ionize to release H^+ (H_3O^+) ions. The tendency to ionize depends on the basicity

Figure 7 Schematic representation of the pores present in a macroporous resin. (Reproduced from Dyer *et al.*, 1997, with permission.)

of the metal atom attached to the OH group, and the strength of the metal-oxide bond relative to the O-H bond. Some materials are able to function as both anion and cation exchangers, depending upon solution pH, i.e. they are amphoteric. Capacities lie in the range 0.3–4.0 meq g⁻¹.

Hydrous oxides of the divalent metals Be, Mg, Zn have exchange properties, usually anionic, often in combination with similar materials derived from trivalent metals.

The most well-known trivalent hydrous oxides are those of iron and aluminium. Both produce more than one hydrous oxide. Examples of the iron oxides are the amorphous substances α -FeOOH (goethite), β -FeOOH, and γ -FeOOH (lepidocrocite). The similar compounds which can be prepared from aluminium are complex, and have been thoroughly researched because of their use as catalyst support materials and chromatographic substrates. Those that exhibit exchange are α -Al₂O₃, α -Al OOH and α -Al(OH)₃. Certain of the Fe and Al oxides are amphoteric; **Figure 8** demonstrates this via a pH titration. This is a common method of study for inorganic exchangers of this type, as well as those in the other classes which contain exchangeable protons. Other trivalent oxides with exchange properties are known for gallium, indium, manganese, chromium, bismuth, antimony and lanthanum.

Amphoteric exchange is known in the hydrous oxides of the tervalent ions of manganese, silica, tin, titanium, thorium and zirconium. Silica gel is particularly well studied because of its use as a chromatographic medium. It has weak cation exchange capacity (1.5 meq g⁻¹ K⁺ at pH 10.2) and can function as a weak anion exchanger at pH ~ 3. Zirconia and titania phases also have been the subject of much interest, particularly for nuclear waste treatment, and manganese dioxide is unique in its high capacity for strontium isotopes.

Hydrous oxides of elements of higher valency are known but only one has merited much study namely, antimony oxide (also called antimoninic acid and hydrated antimony pentoxide, or HAP). This exists in crystalline, amorphous and glassy forms and is an example of a material that is amenable to a reproducible synthesis. It can also be well characterized by, for example, X-ray diffraction and infrared spectroscopy. Many proposed applications have been suggested, especially based on the separations of metals that can be carried out on crystalline and other forms. An example of this is the ability of the crystalline phase selectively to take up the alkaline metals from nitric acid solution where the selectivity sequence is Na > Rb > Cs > K >> Li. HAP has the sequences Na > Rb = K > Cs in nitric acid, Na > Rb >

Figure 8 Titration curve for the titration of a commercial alumina with 0.02 mol L⁻¹: ○, LiOH; ●, KOH; △, HCl; ▲, HNO₃. (Reproduced from Clearfield, 1982, with permission.)

Cs > K in hydrochloric acid. This unique ability to selectively take up sodium finds wide use in neutron activation analysis where the presence of sodium isotopes is a constant hindrance to the γ -spectroscopy vital to the sensitivity of the technique. This is particularly important in environmental and clinical assays.

Acidic salts of polyvalent metals

Amorphous compounds The recognition that phosphates and arsenates of such metals as zirconium and titanium have ion exchange capabilities can be traced back to the 1950s. Around that time studies into the possible benefits of inorganic materials as scavengers of radioisotopes from aqueous nuclear waste were being initiated and amorphous zirconium phosphate gels were developed for that purpose, and used on a plant scale.

Later similar products of thorium, cerium, and uranium were studied, and also the analogous tungstates, molybdates, antimonates, vanadates and silicates. These compounds turn out to be of limited interest, and value because of the inherent difficulties in their sound characterization. In addition they often have a liability to hydrolyse, and these difficulties prompted the search for more crystalline phases of related compounds.

Polyvalent metal salts with enhanced crystallinity The most success in producing crystalline, reproducible and characterizable compounds has been in the layered phosphates exemplified by those of zirconium and, to a lesser extent, titanium.

Zirconium phosphates Extensive refluxing of zirconium phosphate gel in phosphoric acid, or direct precipitation from HF, yields a layered material

Figure 9 Schematic diagram of adjacent layers of α -ZrP; inter-layer water and protons not included. (Reproduced from Williams and Hudson, 1987, with permission.)

with a diagnostic X-ray diffraction pattern. Its stoichiometry corresponds to $\text{Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$ -zirconium bis(monohydrogen orthophosphate) monohydrate, with an exchange capacity of 6.64 meq g^{-1} . It has been designated as an α -phase and given the shorthand notation ' α -ZrP'. Its idealized structure is shown in **Figure 9**; the layers form a series of cavities in which reside protons and water molecules.

Potentiometric titration demonstrates that the structural unit shown above has two replaceable protons. Detailed studies of its cation exchange properties have been done, including determinations of the thermodynamic quantities for the exchange of the protons for most common metals—especially those of Groups 1 and 2. An interesting feature of these studies is the finding that the layer structure expands to accommodate monovalent ions, with the interlayer spacing being a function of ionic radius and water content. Intermediate 'half-full' phases are stable and well characterized. When the divalent ions of the alkaline earths are the ingoing ions a size restriction operates that is a complex function of the hydrated ion size and instability to shed water of hydration.

For these reasons calcium and strontium exchanges proceed, but magnesium and barium exchanges are very limited (if at all). If, however, α -ZrP is first converted to a half-exchanged sodium form, then Mg and Ba phases can be obtained.

Selectivity series have been constructed, with the half-exchanged Na phase (α -NaH ZrP $\cdot 5\text{H}_2\text{O}$) as the initial exchanger, for the alkali metals and the divalent cations of first row transitional elements. They are: $\text{K} > \text{Cs} > \text{Na} > \text{Li}$, and $\text{Cu} > \text{Zn}$, $\text{Mn} > \text{Fe} > \text{Co} > \text{Ni}$. Exchange into ZrP (amorphous and crystalline) from fused salts gives a selectivity series $\text{Li} \gg \text{Na} > \text{K}$.

A more hydrated phase of zirconium phosphate has been prepared with the formula $\text{Zr}(\text{HPO}_4)_2 \cdot 2\text{H}_2\text{O}$, designated γ -ZrP. It has a different arrangement of layers, with the phosphate groups being sited above each other rather than being staggered as in the α -phase (**Figure 9**). γ -ZrP also exchanges protons in two stages, creating half-exchanged materials; the replacement of the first proton takes place at about pH 2–3, and the second above pH 7.

Alkali metal ion selectivities are in the following order at low pH: $\text{K} > \text{Rb} > \text{Na} > \text{Cs} > \text{Li}$, but at high pH this becomes $\text{Li} > \text{Na} > \text{K} > \text{Rb}$. Recently a novel γ -phase containing mixed zirconium phosphate/phosphite layers has been synthesized. This has one replaceable proton, and hence a lower capacity for cation exchange (3.3 meq g^{-1}) than the other layered materials described in this section.

Other layer compounds Layered phosphate materials of the α type have been prepared for titanium, tin and hafnium. Arsenates of tin, titanium and zirconium with similar structures also are known. Only titanium and zirconium phosphates have γ -phases. **Table 2** illustrates the interlayer spacings of α - and γ -phases of tetravalent acid salts.

Intercalates A considerable body of work exists in which workers have shown that layered substances derived from salts of tetravalent acids can readily expand their layers to accommodate organic molecules capable of protonation. They include amines, alcohols, amino acids and metallocene derivative and they have large interlayer distances. **Figure 10** shows the formation of intercalation compounds of α -ZrP containing *n*-alkyl-monoamines.

Other salts of polyvalent acids Cerium phosphate readily precipitates as a fibrous material that can be formed into sheets. This material has attracted interest,

Table 2 Tetravalent acid salts with their interlayer distances

Compound	Interlayer distance (nm)
α-Salts	
Titanium phosphate	0.756
Zirconium phosphate	0.756
Hafnium phosphate	0.756
Germanium phosphate	0.760
Tin phosphate	0.776
Lead phosphate	0.780
Titanium arsenate	0.777
Zirconium arsenate	0.778
Tin arsenate	0.780
γ-Salts	
Zirconium phosphate	1.22
Titanium phosphate	1.16

both as an inorganic ion exchange paper and as a thin-layer material for the separation of inorganic ions. Cerium phosphate can also be prepared in robust granules for column use. Cerium phosphate is semicrystalline, as are the fibrous forms of thorium phosphate, titanium phosphate and titanium arsenate, which have also been prepared.

Salts of heteropolyacids These are the well-known salts of the parent 12-heteropolyacids, having the general formula $H_mXY_{12}O_{40} \cdot nH_2O$, where $m = 3-5$, $X = P, As, Si, Ge$ or B , and $Y = Mo, W, V$ (and others). Their structures have been known from the early days of X-ray single crystal analysis, and are examples of three-dimensional assemblages of linked $[XO_4]^{4-}$ tetrahedra and $[YO_6]^{6-}$ octahedra. The resulting frameworks contains voids large enough to contain replaceable cations.

The two most studied salts are the molybdophosphates and the tungstophosphates. Until recently it was thought that exchange was facilitated by the presence of water in the framework voids, but it now seems that ammonium molybdophosphate (AMP) is anhydrous and that any water noted as present 'as-synthesized' is contained in the solid by capillary condensation. This means that entering cations must be stripped of hydration water. AMP was one of the first inorganic materials to be used to scavenge radiocaesium from aqueous nuclear waste on a plant scale. Ammonium tungstophosphate (ATP) has a similar selectivity. A large number of organic salts of these acids have been synthesized, e.g. di-, tri- and tetramethylammonium 12-molybdophosphate and pyridinium 12-tungstophosphate.

Insoluble ferrocyanides A variety of compounds have been reported with metal cations held in a framework of linked $[FeCN_6]^{4-}$ octahedra. They include those with mixed metal hexacyano anions, and when cobalt is included in the composition a useful exchanger is obtained.

The product can be written as $K_{2(1-x)}Co_x[CoFe(CN)_6]_x \cdot \gamma H_2O$. When $x = 0.6-0.7$, a stable granular material results that has a high selectivity for caesium. It is used to scavenge caesium radioisotopes from waste emanating from the Lovissa Nuclear Power Plant, Finland.

Several other compounds of this type are being investigated for nuclear waste management, and include the potassium and sodium forms of nickel and copper hexacyanoferrates. In these hexacyanoferrates the exchange is restricted to the surface of the exchanger, but even this restriction still gives an adequate caesium capacity (0.35 mmol g^{-1}) and acceptable kinetics.

Aluminosilicates

Clay minerals These are another group of compounds whose structures have been studied since the earliest days of X-ray crystallography. Their structures are composed of layers of linked polyhedra, and a convenient subdivision of their structural types is into those with:

1. single layers;
2. nonexpandable double layers;
3. expandable double layers.

The most common single-layered clays are the kaolins. These have layers of $[SiO_4]^{4-}$ tetrahedra linked by three corners to create sheets. Between these layers are aluminium ions held to the fourth corners of the $[SiO_4]^{4-}$ tetrahedra that provide, on average, three hydroxyls from one layer and one hydroxyl plus two oxygens from the next layer. This results in another layer of hexagonally coordinated aluminium ions resembling those of gibbsite, a natural aluminium hydroxide mineral. In these clays ion exchange can take place at structural defects (broken bonds), or at exposed (edge) hydroxyls. The possibility also exists that a small amount of Al^{3+} , or Fe^{3+} , can isomorphously replace silicon from some tetrahedral

Figure 10 Arrangement of *n*-alkyl monoamines in α -ZrP, illustrating the change in interlayer spacing with increased loading. (Reproduced from Williams and Hudson, 1987, with permission.)

environments. The presence of $[\text{FeO}_4]^{5-}$ entities confers a negative charge on the silica layers, which can then be compensated by exchangeable cations sited between the layers.

Whatever the mechanisms whereby cations are accommodated into single-layer clays, their exchange capacities are low. The minerals can also exhibit a low anion capacity via labile hydroxyl groups.

In double-layered clays the element of structure is that of two sheets of tetrahedra separated by cations. The unexpandable double layer aluminosilicates, like the micas, have isomorphous substitution of aluminium for silicon in the double layers. This creates strong ionic bonding between the negatively charged layers and the interlayer cations. The cations are in an environment virtually water free so ion exchange is difficult, and confirmed mainly to defect and edge effects. The micas, and similar minerals, are examples of exchangers where the potential cation ion exchange capacity, expected from their stoichiometry, is not experimentally achieved. The need for the concept of loading is thereby illustrated.

In the expandable double-layered silicates hydrated cations are held in interlayer positions by weak electrostatic forces between their hydration shells and the silica sheets. Some isomorphous substitution in the tetrahedral layers is present but does not have a major effect on ion exchange behaviour. The loosely held cations are readily exchanged, and the interlayer distance changes as a function of hydrated cation size. Further ingress of solvent is easy. More water, or even organic molecules such as glycols, can penetrate the layers to further swell the structure. Montmorillonites are typical expanding double-layered clays. Examples of cation capacities for the clay minerals are listed in Table 3.

The ability of clays to act as exchangers is, of course, a major property of soils related to their ability to sustain plant nutrients. Incorporation of metals, such as copper and nickel, aids their use as catalysts. Their use as ion exchangers seems to be limited to wastewater treatment by glauconite (green sand), sometimes in manganese form, and often erroneously described as a zeolite.

Zeolites In these aluminosilicate minerals the constituent $[\text{SiO}_4]^{4-}$ and $[\text{AlO}_4]^{5-}$ share all corners to create a three-dimensional framework structure carrying a negative charge. This framework charge is balanced by the presence of cations contained in channels and cavities within the framework. Many zeolites are able to contain a large amount of water in these cavities and channels, which can have void volumes as high as 50% of their total volume. They are known both as natural species and as synthetic

Table 3 Examples of the cation exchange capacities of some clay minerals

<i>Mineral</i>	<i>Capacity (meq g)⁻¹</i>
Single layer	
Kaolinite	0.03–0.15
Halloysite	0.05–0.10
Double layer (nonexpanding)	
Muscovite (mica)	0.10
Illite	0.10–0.40
Glauconite	0.11–0.20
Pyrophyllite	0.40
Talc	0.01
Double layer (expanding)	
Montmorillonite	0.70–1.00
Vermiculite	1.00–1.50
Nontronite	0.57–0.64
Saponite	0.69–0.81

minerals capable of being manufactured on the tonnes scale.

Nearly 100 different frameworks have been crystallographically defined for zeolites, and related structures, each one having a unique molecular architecture. The internal dimensions of their channels and cavities are close to molecular dimensions and this has led to their employment as ‘molecular sieves’ and catalysts. Usually synthetic zeolites perform these functions and thereby make an incalculable contribution to the world economy, particularly in the oil industry. Examples of zeolite structures are provided in Figures 11 and 12.

Most zeolites readily exchange the cations from their voids. This facile process is vital to their utility as both molecular sieves and catalysts, and has been responsible for most of the literature describing their cation exchange properties. Because detailed crystallographic data is available for some zeolites (even including the positions of water molecules within their frameworks), they have been used to model theories of ion exchange kinetics and equilibria.

These minerals can exhibit very high selectivities, with high capacities, and have been extensively studied for use as such, while being restricted by their instability in acid environments. Examples where use can be made of cation exchange properties will be considered in a later section.

Zeolite cation capacities are a function of the extent of aluminium substitution into framework interstices; examples are listed in Table 4. As with the clays, the loading may not correspond to the cation content. The reasons why full exchange cannot be attained in some zeolites is a complex subject – sometimes framework charges are too low to strip hydration spheres, and the ingoing ions (bare, hydrated or even partially hydrated) may be too large to readily

Figure 11 Linkage of Si, AlO_4 tetrahedra to form a chain structure that, when joined in three dimensions, forms the framework of the zeolite natrolite.

pass through the restricting dimensions in the channels. These effects contribute to the 'ion-sieve' effects noted in some zeolites.

Other framework structures Earlier the point was made that adherence to the traditional classifications of inorganic ion exchangers was not entirely appropriate. This has arisen for a number of reasons, a major one being the endless search for novel catalysts. The synthetic routes chosen frequently mimic those of zeolite synthesis with the aim to produce robust framework structures based on the assemblage of coordination polyhedra. Implicit in this is the likelihood that a microporous medium possessing ion exchange properties will result. To date very little attention has been given to the numerous substances appearing from this source in the context of ion exchange, so only a brief survey will be given.

Prominent in the novel frameworks produced by assemblage of tetrahedral units has been the incorporation of $[\text{TO}_4]$ units into zeolite-like structures. Numerous varieties with $\text{T} = \text{P}, \text{B}, \text{Co}, \text{Cu}, \text{Zn}, \text{Mn}, \text{Mg}, \text{Ga}, \text{Ge}, \text{Be}$ have been identified, and some have also been found in nature. The possibility has already been claimed that a new family of anion exchangers can be made with a framework in which an excess of $[\text{PO}_4]^{5-}$ over $[\text{Si}, \text{AlO}_4]^{n-}$ tetrahedra prevails, rendering the framework positively charged.

Discoveries like these have prompted a reassessment of the opportunities to make inorganic 'molecu-

larly ordered solids' (MOS) based on well-understood coordination polyhedra (tetrahedral and octahedral) formed by metals such as Ti, As, Zr, Hf, Nb, Mo, W, V, etc. They will prove a fruitful area in which to pursue the search for selective exchangers.

Other layer structures

Pillared materials Mention has already been made of the exchange of organic molecules into clays and layered phosphates/phosphites. Similar expansions can arise when a large inorganic ion is introduced between the layers. An early example of this was the exchange of a 'Keegin' ion, such as $[\text{Al}_{13}\text{O}_4(\text{OH})_{24}]^{7+}$, into expandable clays. Subsequent calcination leaves

Figure 12 Structure of (A) synthetic zeolite A and (B) synthetic faujasite (zeolites X and Y) showing the internal cavities of molecular dimension. (Each line represents an oxygen and each junction a silicon or aluminium.)

an alumina pillar propping open the layers to 1–2 nm. Again, the intention of this work was to develop wide-pored cracking catalysts. When ion exchange capacities were measured they proved to be orders of magnitude greater than the equivalent amount of alumina. No significant residual capacity arising from the clay was detected. Many similar pillared substances have now been made with a variety of different layered compounds (natural and synthetic) and inorganic pillars. Little is known of their ion exchange properties.

Hydrotalcites The natural mineral, hydrotalcite, is a layered compound of composition $\text{Mg}_6\text{Al}_2(\text{CO}_3)(\text{OH})_{16} \cdot 4\text{H}_2\text{O}$. Synthetic analogues can be obtained with other metals replacing magnesium and aluminium (Co, Ni, Fe for example). They are commercially available as anion exchangers.

Uses of Ion Exchange Materials

Resins

Water treatment The annual production of ion exchange resins has been estimated at 500 000 m³, of which at least 90% goes to industrial water treatment. The various end uses in this area will now be described.

Softening The removal of calcium and magnesium ions from water supplies is a requirement for many industries. Laundries, dye-houses and cleansing plants are examples of specific industries but the need can be generalized to many hot water circuits, heat exchangers and low pressure boilers. Strong sulfonate styrene gel cation resins, in sodium form with 8–12% cross-linking, are the usual choice, but macroporous resins may well be used when the process is demanding in terms of attrition, elevated temperatures or in the presence of oxidizing agents. An example of such

an aggressive environment is in the modern Chlor-Alkali membrane electrolysis cell for the production of chlorine gas and sodium hydroxide. This process also provides an example of the use of a chelating style resin (iminodiacetate, or aminophosphinate) to scavenge alkaline earth ions (see Table 1).

Dealkalization In dealkalization, weakly acidic carboxylic resins, in hydrogen form, are used to meet the limits of calcium and magnesium concentrations needed in feed water to medium pressure boilers. Hydrogen ions released are neutralized by the HCO_3^- and CO_3^{2-} anions present to give carbon dioxide, which remains in solution as carbonic acid. The softening is only partial and sometimes a sodium resin treatment, as above, is added. There may be an ancillary need to attain some demineralization as well which would involve an additional column treatment.

Single-stage dealkalization finds wide application in the treatment of cooling water and water used in the food and drinks industries. Desalination is a dealkalization process. Modern plants use membranes made from ion exchange resins in an electrodialysis cell.

Demineralization Demineralization involves the use of both cation and anion resins to produce 'de-ionized water'. This can be achieved by a two-stage process in which the raw water is first passed through a column containing a strong cation resin (H) form, and then through a strong anion resin (Type I or II). Some ion exchange plants use weak anion resins, and multistage processes or countercurrent variants are available as standard plant.

An alternative, and common, option is to use mixed beds that contain uniform mixtures of strong cation resins (H) and anion resins (OH). Variants of this approach are widely used to 'polish' water previously demineralized by strong cation/anion beds. Now the admixture of resins can be adjusted to cope with the expected load of residual ions from a specific process water, and so meet the heavy demands of water purity essential, for example, for high pressure steam production in power generation. This is the technology of 'condensate polishing' pervasive through this and similar industrial circumstances. It is appropriate to mention here the production of resins to meet the special needs of the nuclear industry. This manifests itself as 'nuclear grade' resins which are themselves of high purity to reduce potential problems that otherwise would arise from leaching of materials capable of being neutron-activated in reactor circuits. These add to the radiation fields in the reactor, create additional decontamination and waste disposal considerations, and do not help in the

general aim to inhibit corrosion. The nuclear power industry constantly strives to reduce potential corrosion in its steam/water circuits. In pressurized water reactors with 'recirculating steam generators' some operators have a target of low ng levels of ionic impurities per kg water used. These reactors use additions to the primary coolant of (a) boric acid to help moderate the fission process and control corrosion and (b) lithium hydroxide, also to inhibit corrosion. They depend on a sophisticated use of resin beds to achieve the desired coolant water chemistry. In the semiconductor manufacturing industry the demands for 'ultra pure' water are even more stringent with targets in the range $\mu\text{g kg}^{-1}$. (Note 'ultra pure water' is usually taken to mean water with less than $\mu\text{g kg}^{-1}$.) Water used in the production of pharmaceuticals also involves the use of high purity water.

In both dealkalization and demineralization the choice between a gel or macroporous resin is again conditioned by the relative aggressiveness of the feed. In some instances additional factors such as high column pressure differentials and the need for fast kinetics will lead to the use of macroporous materials. Additional treatment of demineralized water with a sulfite-based exchanger removes oxygen via the following route:

Removal of organics In this context 'organic' means the complex anions arising from decay products of organic matter and peaty soils. They are mainly derivatives of fulvic and humic acids and can be removed by employment of a macroporous strong anion resin. This was one of the main uses envisaged from the development of resins of this type. Typical waters requiring treatment contain a total organic carbon (TOC) of 2–20 mg of carbon per litre, which can be more than halved by resin exchange.

Nitrate removal The presence of nitrates in water intended as a potable supply, or for the food industry, is a major environmental concern, arising from the use of nitrate fertilizers. The suggested limit is $50 \text{ mg NO}_3^- \text{ L}^{-1}$, and the options open to attain this include microbiological, reverse electrodialysis using nitrate selective membranes, and traditional ion exchange methods.

Ion exchange is the cheapest and most reliable approach, not least because of the wealth of experience and established technology available. It makes use of nitrate-selective resins based on triethylammonium as functional groups. It is thought that the selectivity may arise from a size/shape exclusion effect that encourages the uptake of the small, flat,

nitrate anion in preference to the larger sulfate, and perhaps chloride, ions, with their spherical nature also being a factor.

Waste effluent treatment Prevention of the release into the environment of toxic metals arising from industrial processes has long been a useful application of ion exchange. Typical examples come in the metal finishing industries whereby wash solutions containing chromium and zinc, for example, can be rendered suitable for discharge. Many similar examples can be found in the photographic, paper and metal pickling industries. Some progress has been made in the employment of resins in the recovery of water from sewage treatment plants.

Another area of concern is in the treatment of aqueous nuclear wastes. The use of ion exchange offers the prospect of vastly reducing some problems by volume minimization of the waste form. Resins have high capacities for the trace quantities of hazardous isotopes arising from nuclear fuel production, reprocessing, reactor water circuits, decommissioning, and in 'pond' waters. The latter can be used as a major example where ion exchange materials can be used to scavenge the caesium and strontium radioisotopes that leak into the ponds in which spent fuel rods are stored prior to decladding and reprocessing (see Table 1).

In all nuclear applications the ultimate safe storage of the waste form is of prime importance. Previous practice has often been to store the highly radioactive resins in a concrete pit. Clearly this is undesirable, due to the limited radiation stability of the organic resins, and new approaches are now preferred, either by using inorganic exchangers or by encapsulating the spent resins in concrete. Even encapsulation should be regarded as temporary in the timescales recommended for nuclear waste disposal. The search for suitable inorganic materials has only been realized in a limited area because of reasons that will be considered later. The resin manufacturers are continuing to synthesize nuclear resins, and seek to provide products that can take up radioisotopes with high degrees of selectivity, often by chelating action. An example of this area of work is in the potential use of novel strong base polyvinylpyridine anion resins to remove americium and technetium from nuclear wastes.

Metal recovery Resins often form part of metal recovery processes, both in primary ore processing and from process waste streams. The second of these is becoming of increasing economic importance with the need to create efficient metal 'winning' from low grades ores, tailings, mine wastewater and

mineral dumps. Ion exchange competes with liquid-liquid extraction in these areas, with varying success, and can be used in combination with this process in some instances. Macroporous resins are popular for these applications. Table 5 provides a list of metals that can be recovered on a commercial basis by ion exchange.

Note should be made of the essential role played by resins in aiding the separation of uranium from its ore in nuclear fuel production, whereby uranyl sulfate is loaded onto anion resins from which it is leached prior to solvent extraction to complete the separation process. Solvent extraction is the major separation technique in the process and the same is true of reprocessing, but both anion and cation resins are an essential part of the method whereby purified uranium and plutonium are obtained.

Other applications of ion exchange resins The reader is reminded of the wide use of resins in catalysis, and in the purification of antibiotics, vitamins, nucleotides, amino acids, proteins, enzymes and viruses that have been excluded from this review. One application in the purification of natural substances is the use of a finely sized cation resin to replace sodium and potassium ions by magnesium in sugar refining. Sodium and potassium promote the deleterious formation of molasses that has to be discarded.

Historically the best studied area of ion exchange application has been the use of exchange materials to perform separations to aid quantitative analysis. Originally, in the majority of cases the intent was either to remove interfering ions or to scavenge trace ions onto an exchanger so as to preconcentrate sufficient material for analysis. This work forms the basis of ion exchange chromatography, which has evolved into one of the most useful analytical techniques ever developed, namely high performance ion chromatography (HPIC). In HPIC low capacity ion exchange

materials are used in pellicular form on stable microspheres. Fast uptake of trace quantities of ions is guaranteed and differential elution provides an adequate separation so that individual ions can be recognized by their diagnostic column residence times. This presupposes that a suitable detector can monitor the column effluent to detect the ions in the eluent. Conductivity changes prove to be adequate for most purposes.

An important stage in the development of the technique was the use of suppressor columns that were able to remove the ions present as a consequence of the use of eluents by retaining them on suitable resins, thus greatly improving the detection sensitivity. Highly sophisticated instruments are now able to revolutionize the quantitative trace analysis of cations and anions, both organic and inorganic. The method is highly reproducible, rapid, and able to carry out routine analyses on a diverse range of analytes.

Inorganic Exchangers

Inorganic materials offer the possible advantages of increased thermal, and radiation, stability over their resin counterparts. In some cases, e.g. the zeolites, they can also compete in terms of capacity and in extremely selectivity exchange. These advantages have created great interest in their potential use for aqueous nuclear waste treatment. This is encouraged by the preferences stated by regulatory bodies that inorganic exchangers are preferred for incorporation into the accepted waste disposal forms for medium and intermediate level radioactive waste.

The main problems, some of which have been mentioned earlier, encountered in progress towards this ideal are:

1. the inherent difficulties in developing reliable characterization methods for many amorphous exchangers;
2. the fact that synthesis often results in products with small particle sizes inappropriate to column use;
3. the lack of materials compatible with direct treatment of the acid streams common in, for instance, reprocessing plants, and even the high pH (~ 11.4) encountered in fuel storage ponds;
4. the liability to hydrolytic damage, even under modest pH conditions.

These disadvantages clearly extend to many other non-nuclear areas of potential use where acid or alkaline media need to be treated. Despite these problems there have been some successful uses of inorganic exchangers, as will now be described.

Waste effluent treatment

Nuclear waste Reference has already been made to the earlier use of AMP and zirconium phosphate to scavenge Cs and Sr radio isotopes from nuclear waste streams. Other earlier processes made use of clays, green sand, and amorphous aluminosilicates. These latter materials, marketed as 'Zeolites', resembled the early 'permutites'. The zeolite minerals also were early candidates for use, but often resins took preference until the increased environmental considerations related to the safe disposal of highly active resins became of concern.

Initially studies in the US nuclear industry showed that the natural zeolites chabazite, mordenite and clinoptilolite had high selectivities for strontium and caesium fission isotopes, and these have been developed into modern plants. Examples of these are the use of clinoptilolite in the SIXEP process at BNF, Sellafield, UK, and chabazite at Oak Ridge, USA. A mixture of synthetic zeolite A and chabazite was the main agency used to scavenge caesium after the Three Mile Island accident, and clinoptilolite was extensively used at Chernobyl. Mention should be made of the use of clinoptilolite to reduce the body burden of fission isotopes in living hosts (including humans), and to reduce their presence in crops.

Work in progress on the treatment of high level waste (HLW) to encapsulate a wide range of isotopes, including α -emitters, includes tests on composite exchangers based on inorganic materials in polyacrylic resins. Considered also are ferrocyanides and silicotitanates with framework structures. Zeolites, zirconium phosphate and AMP have been used to obtain pure isotopes for commercial purposes.

Wastewater treatment The ubiquitous occurrence of clinoptilolite on the Earth's surface has created numerous publications describing its use to treat water from sewage plants. Several plants have been constructed to this end, e.g. Denver and Rosemount, USA and Budapest, Hungary. These make use of local supplies, and regeneration steps have been developed. Other areas of the world pursuing this application include Italy, Cuba, Japan and several locations in Eastern Europe. Eastern Europe has also been the major source of literature describing the employment of clinoptilolite to remove toxic metals from effluent streams. In these cases regeneration is not usually an option, that is the processes are 'once-through'. Recently clinoptilolite has been widely used to treat swimming pool water in circulatory systems, with regeneration.

Other areas

Detergency The need to remove hardness from washing water has long meant that a softener ('builder') has been a vital component of commercial deter-

gents. Within the last 10–15 years there has been a move away from the phosphate builders traditionally used. The main agencies chosen to replace them have been synthetic zeolites. Currently the world annual production of synthetic zeolites for this purpose is approaching 1 million tonnes. This is largely as zeolite A, but a synthetic gismondine, zeolite MAP, is an alternative. Zeolites can be incorporated into both powder and liquid detergents, and natural zeolites have been used in cheaper powders.

Dialysis Amorphous zirconium phosphate is used in portable renal dialysis equipment. To remove urea from the dialysate it is first converted to ammonium carbonate by the enzyme urease. The ammonium ion is then taken up by ZrP. In some systems hydrous zirconia has been used to sorb phosphate ions released from the ZrP by hydrolysis.

Perspective of the Field

Despite the emphasis in this article on the combination of chromatography with mass spectrometry (MS), the first applications of MS in organic analysis used a direct insertion probe (from which only a crude sample mixture fractionation could be achieved), or a vapour inlet system in which the volatile samples from a glass bulb were introduced simultaneously into the ion source of the mass spectrometer. Before this, MS was not used for the analysis of organic compounds at all. Pioneers such as Aston (who won a Noble prize for the development of MS and associated instrumentation) and Dempster worked in the early part of the twentieth century on the determination of masses and relative abundances of isotopes. Preparative MS was used in the Manhattan project (carried out by the United States during World War II) to separate the isotopes of uranium, and accumulate enough fissionable material to create the first atomic bombs. A short description of the Calutrons that were used, which are based on sector instruments and still used for isotopic enrichment, is given later.

If each and every compound provided a unique retention time (or a unique set of retention times on different columns) when subjected to column chromatographic separation, only the most general detection method would be required, since the retention times alone would suffice to establish compound identity. Conversely, if MS provided a differentiating mass spectrum for each and every compound, then no separation of mixture components prior to spectral analysis would be required. Any measured mass spectrum could simply be deconvoluted as the sum of individual mass spectra. Reality destroys these idealistic dreams, as even simple mixtures can sometimes confound analytical methods used to characterize them. Approaches to mixture characterization are always based on many independent analytical data sources. The more complex the mixture, the greater the individual differentiating abilities of the methods applied must be, and the greater their independence should be. Modern column chromatography (meaning capillary column

gas chromatography, microcolumn liquid chromatography, and capillary electrophoresis) provides extraordinary separations for complex mixtures. There must still be a detector to trace the elution of separated components as they elute from the column, and a nonspecific detector would suffice if the separation were perfect and distinctive. But even with the capabilities of modern chromatography, given a completely random set of compounds in a mixture, overlaps in retention time can be expected for as few as 15–20 components. For a set of related compounds, the overlap could reasonably be expected to occur at a lower number of components. At this point, the analyst must turn to the results of measurements provided by the independent detector to provide some differentiation. Consider the various detectors used in gas chromatography (GC). The thermal conductivity detector, the flame ionization detector, the electron-capture detector, and the nitrogen/phosphorous photometric detectors represent a graduated series from the more general to the more specific. But use of these detectors in and of themselves does not provide the data needed to identify a compound that elutes at any given time. They provide information that is necessary, but not sufficient, for compound identification. GC coupled with infrared (IR) or nuclear magnetic resonance (NMR) spectroscopy provides more specific information. However, the highest degree of differentiating power, clear independence from chromatography, and the greatest ease of interfacing to the chromatographic column, is provided with the use of MS. The analytical authority of combined chromatography-mass spectrometry is reflected in the pervasiveness of the method and its standing in legal and regulatory venues. This article provides a rational overview of the analytical principles of these methods as a combined analytical tool.

Technology Overview

Technological secrets are the most fleeting of all, as both scientists and engineers are inquisitive about and insistent upon the latest analytical instrumentation. The ubiquity of combined chromatography-mass spectrometry results in a competitive commercial market for such instruments. Manufacturers strive continuously for both substantive and incremental improvements. Hardware/software configurations that do not compete effectively, or do not meet

the current analytical need, are soon relegated to obscurity. This rush to sophistication often obscures the history of instrumental/methods development. However, the end result of this evolving but continually renewed market is an installed base of instrumentation that can be described in broad brushstrokes, and that is the purpose of this section.

Separation Methods

This section begins with a brief overview of the aspects of separation methods that are of general concern in the interface to MS. Then each subsection covers traits that are specific to particular methods. As a sample introduction system, the purpose of the chromatography column is to transport single, separated components of the mixture efficiently and completely into the source of the mass spectrometer. The relevant questions are therefore simple. How much material is transported? How fast is it coming through? In what form are the sample components? How well is each component separated in time from other components of the mixture? To summarize, these issues are scale, flux, phase, and purity. Therefore, the descriptions that follow will not be comprehensive overviews of how the various chromatographic interfaces to the mass spectrometer were developed or how they are operated, but will concentrate on these four central issues.

Gas chromatography The characteristic of GC that makes the interface to MS (electron ionization (EI) and chemical ionization (CI)) especially straightforward is the fact that the sample molecules are already in the gas phase, and that they are transported into the source of the mass spectrometer by a carrier gas with substantially different physical characteristics from those of the sample molecules themselves. In packed column GC, the flow of helium carrier gas was so high under the conditions normally used for separation that an 'enrichment' device had to be used to remove most of the helium, and therefore increase the concentration of sample molecules in the gas flow entering the source. The higher diffusivity of helium gas formed the basis for most of these separators. As higher pumping speeds became available with improved vacuum technology, and as the use of capillary column GC cut the flux of helium into the source of the mass spectrometer by a factor of ten, it was found that the flow of helium gas (and entrained sample molecules) could be handled directly by the improved pumping in the source of the mass spectrometer, maintaining the pressure at 10^{-5} – 10^{-6} torr.

The helium was present in the source in excess, but the low mass of helium was an advantage in that most

mass spectra were recorded only to a lower mass limit of about m/z 45. So the ions from helium were not recorded, and neither were ions from nitrogen, oxygen, argon, water, and carbon dioxide, all of which constituted residual molecules in the vacuum system. As there was no separate enrichment device, the efficiency of sample transport into the source was 100%, and the sample molecules were in the gas phase. As packed columns were replaced by capillary columns in GC, the influx of sample molecules changed from nanogram–microgram levels of sample per peak to picogram–nanogram levels of sample per peak. Higher amounts of sample overloaded the capillary column, and compromised separation, but these picogram–nanogram amounts of sample material were still within the detection range of the mass spectrometer. As the widths of the peaks in capillary columns were decreased relative to the widths generated by packed column chromatography, the flux in terms of amount of material(s) was still similar, even though the total amount of material was reduced. Of course, with reduced peak widths and higher separation resolution, the chances of any given peak being completely resolved were also increased. Issues that remain relevant are the need to scan the mass analyzer fast enough that representative mass spectra of a narrow peak can be recorded, and the increased demands upon a data system that is called upon to record thousands of mass spectra for hundreds of resolved sample mixture components.

Liquid chromatography Interfaces for liquid chromatography–mass spectrometry (LC-MS) must deal with transport issues that are additionally complicated by the fact that the sample is a solute in the liquid phase, the transfer into the gas phase produces large volumes of solvent vapour, and the samples are likely to be those that are relatively nonvolatile in the first place (otherwise GC would be used). Although the separation resolution may not be as high as in the best capillary GC, peaks are usually still only a few seconds wide and the amount of sample to be transported is also in the picogram–nanogram range, so the flux of material into the source is similar to that in GC-MS. The purity of the sample assessed relative to other mixture components is also similar, with separations designed to produce clean, well-resolved peaks. However, the solvent is often a mixture (as in reversed-phase gradient LC) and buffers and additives may be added to the solvent system. There is a background signal contribution from these components, and this contribution may change during the course of a chromatographic separation. As detailed in the appropriate sections, EI and CI MS act upon sample molecules in the gas phase. This is not the

form in which the sample molecules are found in LC, and it is difficult to transfer nonvolatile sample molecules into the gas phase without thermal degradation. Several ionization processes have been developed that do not rely on the sample being in the gas phase. Thermospray ionization, continuous flow fast atom bombardment, and discharge ionization sources have been developed and optimized. However, the most widely used ionization method is electrospray ionization (ESI). In this technique, a combination of progressive desolvation and field-assisted ion extraction creates a series of multiply charged ions from the sample molecules, even if those sample molecules are 'nonvolatile' and thermally fragile. The flow and flux ranges accommodated by the ESI sources overlay the range of flow and flux in modern LC, endorsing the combination.

Capillary electrophoresis In capillary electrophoresis (CE) the movement of sample molecules (often charged, but neutral molecules move through the column as well) is induced by a combination of electrophoretic and electroosmotic flow. The small differences in mobility exhibited by molecules result in different retention times within the 0.5–1-m-long columns usually used. These columns have a small diameter (50 μm) capillary to efficiently dissipate the heat produced by the high potential difference (30 kV, for example) between the front and the back of the column. The flow profile in the column is not parabolic (as in pressure-driven systems) but is essentially flat, leading to very high resolution separation. There are few instances of overlapped peaks. The small column diameter limits the amount of material that can be loaded onto the column, with loadings 10–100 times lower than in LC. Peak widths are still a few seconds wide, so the instantaneous concentration of sample is lower than in GC or LC. A small volume of sample solution (picogram–nanogram levels of sample in 10 nL of solvent) is injected at the positive end of the capillary and the separated components are detected near the negative end of the capillary. Detection is accomplished with all of the same detectors as in LC, including mass spectrometers. However, the dynamic ranges of CE and MS are not as extensively overlapped as in GC or LC coupled with MS. Despite the general assumption that MS is the most sensitive detection method in use, laser-induced fluorescence detection provides lower limits of detection than MS, but not, of course, with the same specificity. As in LC, the sample molecules of interest are not amenable to evaporation, and so ESI is most often used with CE. In fact, the electrical requirements of the capillary electrophoretic separation often dovetail nicely with

the requirements for the ESI source (*vide infra*). As noted, sample peak purity is usually high because of the extraordinary resolution achievable with this method, and detection may be simplified so the solvent (often methanol) background contribution is simple and often suppressed relative to the signal from the sample.

Ionization Methods

The mass analysis step in MS requires the interaction of charged ions with magnetic or electrical fields, and therefore a means must be found either to create ions from neutral molecules, or to extract ions from a sample solution and transfer them to (or isolate them in) the gas phase. The ionization source in the mass spectrometer accomplishes this task. In mass spectrometers that interface to various methods for separation, particularly column chromatographic methods, only three ionization methods are used for the majority of applications, and will form the focus of the discussion here. EI dates back to the first developments of MS, and is the basis for the extensive mass spectral libraries available. CI was developed in the mid-1960s and is a powerful adjunct to EI. It is especially useful for the determination of molecular masses of compounds that fragment extensively under EI conditions. ESI is more recent in origin, and produces a different type of mass spectrum. Matrix-assisted laser desorption ionization (MALDI) is an even newer ionization method with special applications to high mass biomolecules. As separation methods are developed for separation of truly high mass biomolecules, and mixtures of such compounds, MALDI may become as common an ionization method as the others described in this section. Note that both EI and CI deal with sample molecules in the gas phase, while ESI brings charged species directly out of a liquid solution, and MALDI generates sample-related ions from a mixture of the solid sample and an energy-absorbing matrix.

Electron ionization EI was the first ionization method developed for MS, and it remains the most widely used. The term 'electron impact' is still also used, and the acronym EI covers both terms. Importantly, the most extensive mass spectral libraries assembled are those of EI mass spectra recorded under a 'standard' set of conditions (70 eV electron energy). The gas that flows into an EI source (helium from a gas chromatograph, for example) is confined so that the gas-phase sample molecules interact with the electrons emitted from a metal filament. A high conductance of un-ionized, neutral sample molecules out of the source must also be maintained to minimize cross-peak contamination. EI sources are maintained at

a temperature of about 200°C to prevent condensation of sample molecules on the source walls.

The ionization process is the direct result of the interaction of an energetic electron with the sample molecule. The electrons are emitted from a filament through which 3–4 A of current is passed to heat the filament to about 2000°C. Electrons are accelerated into the source by maintenance of the electron filament at a potential more negative than that of the source itself; a potential difference of 70 V (therefore 70 eV) is standard. Then electrons travel across the source to the trap where they are collected and the current is amplified. The trap is used as part of the feedback loop to maintain a constant emission of electrons from the filament. This current is usually about 100 μ A (about 6.25×10^{14} electrons per second). Only a small fraction of the electrons passing through the ion source participates in ionization of sample molecules, and only about 1% of the sample molecules are ionized in EI. The EI process can be written for the gas-phase sample molecule M:

The molecular ion $\text{M}^{+\cdot}$ (the dot denotes an unpaired odd electron) may subsequently dissociate, since EI imparts more energy to the gas molecule M than is required for ionization alone. The excess energy can cause the dissociation of the molecular ion $\text{M}^{+\cdot}$, or it can be retained in the ion as excess internal energy. Since an electron is far too light to transfer kinetic energy to the sample molecule in a collisional process, the process of EI involves only electronic excitation of M. The molecular ion $\text{M}^{+\cdot}$ retains the original structure of the molecule M, at least for a short time after its formation. If dissociations of the molecular ion are prompt, therefore, we can assume that the dissociations represent those of the original molecule and not a structurally reorganized isomer. Some molecular ions formed will be stable enough to pass through the mass spectrometer and reach the detector. Their measured m/z ratio is a direct indication of the molecular mass of the sample molecule itself. For those molecular ions that dissociate, the fragment ions that form are produced from a structure that is a direct analogue of the molecular structure. Clues to the original structure can thus be obtained by piecing together or rationalizing the processes that lead to fragmentation.

Chemical ionization In EI, if too much energy is deposited into the $\text{M}^{+\cdot}$ ion during the ionization process, or if the molecule is especially prone to dissociate, fragment ions may be seen in the mass spectrum, but the $\text{M}^{+\cdot}$ may be reduced to such a low intensity that it is indistinguishable from the back-

ground signal level. Without the molecular ion, the determination of molecular mass is difficult. CI was developed to overcome this difficulty and provide molecular ions for such compounds. CI involves a collision and reaction between an ion and a gas-phase sample molecule. The ion is called the reagent ion and the molecule is the gas-phase neutral sample molecule. There is no common and standard set of operating conditions for measurement of CI mass spectra such as exists with the EI source. As a result, there is not a large CI spectral library, and interpretation of CI mass spectra depends more heavily on the skill and experience of the user.

The CI source is a variation of the standard EI source, with modifications required to achieve a higher source pressure (about 1 torr) while keeping the mass analyser pressure within acceptable limits. Methane is a common CI reagent gas, and the reagent ion CH_5^+ will transfer a proton to the gas-phase sample molecule to form $(\text{M} + \text{H})^+$. The protonated molecule is relatively stable, and can usually be observed in the mass spectrum of a compound for which the molecular ion $\text{M}^{+\cdot}$ formed by EI cannot be distinguished. The source filament is still heated to a high temperature so that electron emission occurs, but in CI the electron energy is usually 250–500 eV; the higher energy allows the electrons to penetrate through the high pressure in the source. The gas pressure caused by sample molecules is still about 10^{-5} – 10^{-6} torr, just as it was in the EI source. As the pressure of methane is 1 torr, in an equal source volume, the electron emitted from the filament is much more likely to encounter a methane molecule. When it does, an EI process occurs, namely:

The $\text{CH}_4^{+\cdot}$ ion does not travel far before it encounters a neutral gas molecule, and at 1 torr of methane and 10^{-6} torr of sample, the molecule it encounters will most likely be a methane molecule. The next reaction creates CH_5^+ and CH_3 . Several other reactions occur, and the final distribution of ions depends explicitly on the source temperature and pressure. The primary reactant ion for methane reagent gas is usually CH_5^+ , and this ion acts as a strong gas-phase acid that protonates anything more basic than methane. The sample molecules are sufficiently basic to accept a proton to form the protonated molecule. The protonated molecule then fragments in accordance with the amount of internal energy it contains. In most cases not all of the protonated molecules fragment, and since there is an observable signal for the protonated molecule in the mass spectrum, the molecular mass of the sample compound can be established. The

fragmentation processes in CI are different from those observed in the EI mass spectrum, since the $(M + H)^+$ ion is an even-electron rather than an odd-electron species. The pattern of fragment ions is still interpreted to support a structure for the sample molecule. Other reagent gases form ions that transfer protons to the neutral sample molecules, forming an ion of the same mass but with a different amount of internal energy. The protonated molecule therefore fragments to a different extent. The degree of fragmentation of the sample molecule can be 'tuned' by choice of the reagent gas, and this experiment can be useful in interpretation of CI mass spectra.

Electrospray ionization In GC, helium carrier gas that enters the source along with the vapours of the sample does not disrupt the EI or CI process. However, both LC and CE separate species in a solvent, and the sample enters the ionization source along with a continuous flow of solvent (aqueous or organic) that generates a tremendous amount of solvent vapour. If EI or CI are to be used, the bulk of the solvent must be removed without loss of the sample, as the great excess of solvent vapour will certainly affect the ionization process. Various means have been devised to accomplish this task, but the efficiency is low and the process cumbersome and subject to many complicating factors. ESI allows ions to be created directly from the sample solution, and conveniently at atmospheric pressure. In ESI, the mechanical need for solvent removal is greatly reduced, albeit at the cost of allowing only a small continuous flow of solution to enter the mass spectrometer.

In ESI the sample solution is passed from the LC column or CE column through a connection junction into a short length of stainless steel capillary. A high positive or negative electrical potential, typically 3–5 kV, is applied to this capillary. There is clearly a need for electrical isolation in the LC connection, and potential management in CE. As the solution is forced to flow through the capillary tip, the solution is nebulized into a spray of very small droplets. This spray is formed at atmospheric pressure. The mass spectrometer operates at a vacuum of 10^{-5} – 10^{-6} torr. The pressure must therefore be reduced before the droplets (and the sample species that they contain) enter the mass spectrometer. The spray of droplets is usually directed through a skimmer that provides a differential pressure aperture, and also acts as a momentum separator. As the droplets move through this region, neutral solvent molecules evaporate rapidly and the droplets become progressively smaller. As droplets leave the charged capillary needle, most of them retain an excess of positive or

negative electrical charge, corresponding to the potential applied to the capillary. This excess charge resides on the surface of the droplets. As the droplets get smaller, the electrical surface charge density increases until the natural repulsion between like charges causes ions as well as neutral molecules to be expelled from the droplets. This field-induced evaporation also forces the droplets to become progressively smaller. Note that ions themselves cannot evaporate from the droplet. However, if the charge density is high, a Coulomb-force-induced 'explosion' can expel them from the droplet. As solvent molecules evaporate from the droplets they diffuse in all directions, while the higher momentum, charged droplets are directed towards the first skimmer, and then (usually) through a second concentric skimmer that lowers the pressure even further, by a combination of momentum separation and steering potentials applied to the skimmers. In some ESI sources a drying gas (nitrogen) flows along and past the end of the capillary and skimmer to assist with evaporation of the solvent from the droplets. The end result of the electrospray and progressive desolvation process is a stream of ions that have been extracted directly from the solution in which they were originally found.

If sample ions are already present in the solution then it is clear that these ions can be sampled directly. Solvents used in LC and CE also have appreciable ion concentrations, especially as buffers and ionic modifiers are often present in the solutions. In most cases, there is a substantial free proton population. Protons will not evaporate from the droplet as it becomes smaller; the 'pH' rises inexorably as the droplet becomes smaller. During the last stages of solvent evaporation, the protons will be forced to associate with the most basic molecules remaining in the droplet. This is not necessarily an acid–base equilibrium situation, because the dynamics of desolvation and sampling play a large role. However, the situation can be considered as one in which a free proton (a strong acid) protonates the sample molecule, which is forced to act as a proton acceptor. Other Lewis acids (cations) present in the droplet act similarly. There is a transition from the lower concentrations of ionic species present in the bulk solution to the near 100% ionic population present in a nanodroplet. The 'pH' drops to such a low value that multiple protonation is common.

The unique nanodroplet environment from which ions are drawn in ESI provides a route to highly protonated, multiply charged ions. It is the formation of multiply charged ions that makes ESI valuable for examination of sample molecules of high molecular masses. In EI and CI, most ions are formed with a single positive or negative charge. The x-axis of the

mass spectrum is the m/z ratio, and z is one. Therefore the mass on the ' m/z ' axis is directly indicative of the sample molecular mass. In ESI, values of z greater than one are commonplace. ESI-derived positive ions are found as $[M + nH]^{n+}$, where n ranges from 2 to 30, and is sometimes as high as 100. Several factors contribute to the propensity of ESI to create multiply charged ions. The first is the strongly acidic environment of the nanodroplet. The second is the fact that higher molecular mass molecules are, quite naturally, large molecules, and larger molecules can accommodate a greater number of protons. For a protein, for example, a basic amino acid residue will be the site associated with the proton. Basic amino acid residues will be far enough apart in a typical protein that the protons add independently, and there is minimal Coulombic repulsion between the charged sites. The higher order structure of the protein will therefore determine what sites are accessible for protonation, and this characteristic is the basis for some of the most intriguing and revealing ESI experiments.

Suppose that M , the molecular mass of the sample molecule, is 10 000 Da. In ESI, the $(M + 20H)^{20+}$ ion may be formed. This ion has a mass-to-charge ratio of $(M + 20H)^{20+}$, and therefore $m/z = 10\,020/20 = 501$. This mass is well within the range of the mass spectrometer, and can be determined accurately. Usually several different forms of the multiply charged ions are found, namely $(M + nH)^{n+}$, with a distribution of intensities. Each successive molecular ion contains one more proton and therefore one more charge. The series is easy to identify, and the value of n need only be determined for any one ion for the entire ion series to fall into place. The value of n can be determined from the spacing of isotope peaks in the molecular ion isotopic envelope, and the derivation has now been fully automated. The mass spectrum that contains the array of multiply charged ions is plotted in terms of the m/z values of those ions. But M is the same for each of those ions, and each ion is a slightly different pointer to that value of M . Having determined the masses of each of the multiply charged ions, the series of equations can be solved to determine the value of M . The data can now be presented as a transformed spectrum with one molecular ion, M . If there is more than one sample molecule M , the m/z spectrum can appear extraordinarily complex, but the transformed mass spectrum clearly shows the presence of multiple components (although the relative intensities may not accurately reflect the solution concentrations of the sample molecules).

Matrix-assisted laser desorption ionization The title of this section reveals MALDI as the most 'matrix-

dependent' of the ionization methods discussed in this overview. This should not be surprising, as the ionization usually occurs from a solid-phase mixture of sample molecules in a large excess of energy-absorbing matrix molecules. Therefore, MALDI would appear to be the most ill-suited of the techniques discussed for interfacing to column chromatographic methods. However, effluents from LC separations have been deposited onto collection surfaces, and then the trail in space (along the x -dimension, for example) analysed by MALDI to provide the corresponding trace of sample elution in time. MALDI has also been applied to planar separation methods such as thin-layer chromatography (TLC) and gel electrophoresis. As interface technology improves, a miniaturized solid surface may be used to intercept effluents from columns. This may be a particularly attractive interface since MALDI, in conjunction with a time-of-flight mass analyser, has been shown to be a very capable ionization method for the production of simple mass spectra of very high mass biomolecules. Column chromatography will increasingly be used to perform separations of mixtures of such molecules, although not necessarily in the forms described previously in this section, and MALDI may be used increasingly in such applications.

Mass Analysis Methods

Each of the ionization methods discussed here has characteristics that affect the design and operation of the interface between chromatography and MS. Similarly, methods of mass determination affect the overall analysis, but not as directly. In most standard operating protocols, the data processing has assumed primary importance, and the details of the instrument on which the mass spectra were measured are hidden. This current state of affairs is in direct contrast to the situation 20 years ago, when there were distinct differences in mass spectra measured with quadrupole and sector instruments, and specific means were undertaken to normalize the mass spectra for purposes of library matching and identification. Similarly, scanning speed advantages of the quadrupole over the sector were an early boost for the former's incorporation into GC-MS instruments. Additionally, the high source potential of sector instruments made some of the early LC-sector MS designs problematic. Each of these technological hurdles has been overcome. With the introduction of the ion trap mass analyser, benchtop instruments for both GC-MS and LC-MS are becoming still smaller and even vehicle-portable. It is useful to briefly review attributes of each of the common methods of mass analysis. Simplified schematics for each of the mass analysers discussed are presented in Figure 1.

Figure 1 Simplified schematic drawings of (A) a sector mass spectrometer; (B) a quadrupole mass filter; (C) an ion trap; (D) an ion trap incorporated into a complete system; (E) a time-of-flight mass spectrometer.

Sector mass analysers The term 'sector' mass spectrometer refers to instruments in which the mass separation of the ions is accomplished by passage of the ion beam through a magnetic field directed perpendicular to the direction of ion motion. At any given magnetic field strength, ions of different mass follow trajectories of different radii. Given an equal kinetic energy for all ions, lower mass ions will trace a path of lower radius than higher mass ions. A narrow slit allows only those ions whose path follows a radius equal to that of the magnetic sector itself to pass through to the detector. Scanning the magnetic field strength passes ions of different mass to the detector. The scanning speeds of modern electromagnets are such that a mass range of 10–1000 Da is accomplished within about 0.3 s. Sev-

eral complete spectral scans are therefore recorded for a typical chromatographic peak. A double-focusing sector instrument (a magnetic sector used in combination with an energy-analysing electric sector) provides higher mass resolution, that is, the m/z values of the ions can be measured to an accuracy of several decimal places (e.g., 131.12 Da). Such information can be useful in unambiguous identification of compounds as they elute from a chromatographic column. Based as they are on 'sectors' of electromagnets, these mass spectrometers tend to be larger than other types of analysers, although a significant downsizing is apparent in the current generation of sector instruments. The larger size is reflected in the higher initial costs of such instruments, and therefore sector instruments are usually not the

instrument first acquired by an analytical laboratory for chromatography-mass spectrometry. In collection of data, scanning speed is not usually an issue except for very high resolution chromatography. In selected ion-monitoring experiments, a sector instrument takes some time to hop from mass to mass, whereas a quadrupole instrument (for example) makes the transition instantaneously. Again, this is only an issue in the most exacting of experiments.

Finally, the sector-based mass analyser is used as part of a beam instrument, that is, a device in which the ion beam physically moves through the instrument from ion source to ion detector. In certain geometries the sector instrument is configured such that, at any given magnetic field strength, ions of only one mass are able to pass through the detector slit and reach the ion detector. In this characteristic the sector-based instrument is similar to the quadrupole instrument, although the latter provides a lower resolution and abundance sensitivity, and provides no transport discrimination against neutral species. The fundamental difference from ion trap and time-of-flight mass analysers will become apparent as the principles of operation of those analysers are described. Since the sector-based instrument provides a physical separation of an ion beam of one mass from an ion beam of a different mass, it can be used for the separation and collection and subsequent enrichment of that mass-selected isotopic species. The Calutron is a physically large magnetic-field mass spectrometer built to separate isotopes, with a mass throughput orders of magnitude greater than in a conventional analytical instrument. Preparative-scale MS was used at Oak Ridge as part of the Manhattan project during World War II. Several of these mass spectrometers were constructed and operated in parallel, with production reaching 200 g per day of 88% enriched ^{235}U . Two stages of enrichment were carried out on two different series of 180° sector preparative mass spectrometers, called the alpha and beta series, arranged in racetracks. These instruments maintained beam currents a billion times more intense than those in modern analytical mass spectrometers. More recently, electromagnetic isotope separation was at the cornerstone of an Iraqi programme to develop nuclear weapons. Estimates are that between five and ten billion US dollars was spent on this programme between 1981 and 1991 at Tuwaitha and Tarmiya. Initial devices used for electromagnetic isotope separation could develop a 0.5 mA beam of U^+ ions at 35 keV energy. Production devices were designed to operate with a 150 mA beam current through 1-m-radius magnets. Such uses represent exploitation of the same basic principles used for organic analysis using chromatography-mass spectro-

metry, with an emphasis on production of isotopes rather than production of analytical information.

Quadrupole mass filters A quadrupole mass analyser (more accurately a mass filter) consists of four rigorously parallel rods of hyperbolic or circular cross-sections, and lengths of about 20–25 cm. The ions pass through this rod structure. Opposite pairs of rods are connected electrically. A voltage composed of a direct current (DC) component and a radio-frequency (RF) component is applied to the rods. Relatively slow-moving ions (kinetic energies of 10–50 eV) move from the source into the quadrupole. They are attracted first to one rod, and then to the adjacent rod as the voltages applied to the rods change (the RF frequency). This induced oscillation in the ions results in a spiral trajectory of increasing xy magnitude as the ions move through the rods in the z direction. At a given ratio between the DC and RF voltages ions of only one mass pass completely through the quadrupole rod structure to the detector, while ions of all other masses follow trajectories that result in their collision with the rods. Scanning the magnitude of the DC and RF voltages, while keeping the ratio of the DC and RF voltages constant, allows the mass range to be scanned at a constant mass resolution.

Both the resolution and the scanning speed of the quadrupole mass filter are controlled electronically (rather than physically as with sector instruments) and can be changed quickly. In the 1970s, the much faster scanning speed of quadrupole mass filters compared with the sector instruments catalysed the development of the first viable commercial GC-MS instruments. Since that time, quadrupoles of ever increasing performance have been developed, and many entry-level instruments are based on their use.

Ion traps The ion trap consists of two end caps and a ring electrode to which DC and RF voltages are applied. Ions are formed during a short ionization pulse, after which they are forced to oscillate in stable orbits in the interior volume of the trap. The ions are kept near the centre of the trap by repeated collisions with a low pressure of helium 'buffer' gas, which removes any excess energy and relaxes the ions into stable orbits. Ion traps can be used to trap ions for extended periods of time for various purposes, including ultra high resolution accurate mass measurement. In an ion trap used in a chromatography-mass spectrometry instrument, however, the ions are trapped for only a short period of time. To scan the mass spectrum, the ions are forced out of their stable orbits to a detector by increasing the amplitude of the RF. Ions of appropriate mass (e.g. orbits of a matched

frequency) reasonably absorb that energy. These ions become 'unstable', and trace an orbital trajectory of increasing radius until they are ejected into the detector located just outside the ion trap. As with the quadrupole mass filter, resolution and scan speed (and ion excitation for other experiments) are adjusted electronically. The ion trap itself is very small (contained within a 10 cm × 10 cm × 10 cm volume), and its associated vacuum and hardware components are assembled into a compact, low-cost benchtop unit.

Time-of-flight mass analysers The time-of-flight mass analyser is a racetrack for ions. In its most simple linear form, it is a tube approximately 1 m long. The ions are formed in a short pulse and then accelerated into the flight tube with a potential drop of a few thousand volts. Given equal kinetic energy, ions of different mass will travel at different velocities. The lighter ions are speedy, while the heavier ions lag behind. Ion arrival time at the detector is converted into a mass value by a simple equation. The resolution is relatively low because of spreads in ion velocity (and therefore flight time) derived from other sources, but the mass analyser is exceedingly simple and robust, and provides a complete mass spectrum with every pulse of the ionization source. There is no scanning involved. While other mass analysers (sectors, quadrupole mass filters, and ion traps) are used with every form of column chromatography, the time-of-flight mass analyser is used almost exclusively with MALDI and therefore has been used mostly with planar chromatographic methods of separation.

Data Processing in Chromatography–Mass Spectrometry

A chromatography–mass spectrometry file contains far more data than is usually extracted and displayed to solve a specific analytical problem. However, the specific analytical problem may be restructured, or additional questions may be asked based on the answer to the first question. It is not uncommon for a data set to be interrogated several times. Further, there may be good laboratory practice or regulatory issues that require data storage for extended periods of time. The analyst usually expends far more time in data processing than in data acquisition, especially as the latter may be automated, and the former should never be. Therefore, the focus here is on elements of data processing and interpretation that are affected by the conjunction of chromatography and MS, and in how the information derived from one augments the other.

Synergism in a Hyphenated Method

The result of the linkage between two independent procedures in a hyphenated method can be treated rigorously through information theory. In essence, both methods provide a means to characterize the components in a mixture, but the information provided by one method is independent of that provided by the other. In GC-MS, for example, the retention time of a particular component does not determine the distribution of ions in the mass spectrum. There are special traits that characterize the combination of chromatography with MS, many of which will become apparent in the following discussion. Oddly, the nomenclature for hyphenated methods sometimes includes the solidus rather than the hyphen, so one finds 'GC/MS' rather than GC-MS. The end user seldom redesigns instrumentation, makes any fundamental changes in standard operating procedures, or argues the correctness of nomenclature. The end user spends most effort gathering, analysing, and interpreting data.

Time Basis of Mass Spectral Data

Column-based chromatographic methods continuously elute sample into the ionization source of the mass spectrometer. For the most part, ionization sources also operate in a continuous fashion, generating an uninterrupted stream of ions for mass analysis. However, most mass analysers do not provide continuously measured mass dispersion. The mass range selected by the user is scanned. Usually, the mass analyser scans from a high mass to a low mass. At any given instant, ions of only one mass-to-charge ratio are passed through the mass analyser to the detector, which registers the arrival of the mass-selected ion as an electrical signal. Ions that do not possess the 'correct' mass-to-charge ratio at that particular instant follow a flight path that brings them into collision with some part of the instrument. The ions that are not selected are neutralized at the surface, and the deposited material eventually desorbs from the surface, diffuses through the vacuum, and is removed from the instrument by the vacuum pumps. The consequence of analyser scanning is that only a small fraction of the molecules that are ionized in the source proceed successfully through the mass analyser to the detector to produce a measured signal. It is the extraordinarily high gain (10^6 – 10^8) available with modern electron multiplier detectors that compensates for the inherent 'transmission inefficiency' associated with a scanning mass analyser.

Therefore, in a hyphenated chromatography–mass spectrometry method, the time behaviour of the data as established by the chromatography is convoluted

with the time behaviour of the data as established by the operation of the mass spectrometer. The latter is usually determined by scanning, but in the past was sometimes delineated by how fast the data could be captured and stored. In the ideal analytical design, the chromatography time base would predominate, and the time evolution of the data would be biased at least 100 : 1 in favour of the chromatographic determinant. In practice, the ratio is much closer to 10 : 1, and the time bases for operation of the mass spectrometer should be of constant concern in analysis of the data.

Procedures for Data Processing in Chromatography–Mass Spectrometry

A data set acquired with a GC-MS device will be used as the base to describe the common procedures of data processing in chromatography–MS. In GC-MS, samples are eluted into the source of the mass spectrometer at their characteristic retention times. For a Gaussian-shaped peak, the concentration of the sample in the source starts at a low value, increases to its maximum value, and then decreases symmetrically. Part of the challenge of MS is to record a characteristic mass spectrum for this sample of constantly changing concentration, given that a certain amount of time is required to scan the mass filter across its mass range. Modern mass spectrometers (considered here to be quadrupole, sector, or ion trap mass spectrometers) scan across the usual mass range in a short time. The instrument specifications for a sector instrument may show that the scan speed of the mass analyser can be as fast as $0.1 \text{ s decade}^{-1}$. In this context a decade is the mass range between 10 and 100 Da, or similarly between 100 and 1000 Da. In a sector instrument the scanned parameter is the magnetic field strength, and the ion m/z passing through the instrument varies with the square of this value. In a quadrupole or ion trap instrument, the scan parameter is linearly proportional to the mass of the ion in the analyser.

Approximately ten scans of the mass analyser are required to characterize any GC peak. This requirement stands regardless of the width of the GC peak, and, as the peaks in GC narrow with the achievement of higher separation resolutions, the requirements on the scan speed of the mass analyser become more onerous. Changing concentration of the sample in the source will distort the true intensities of the ions observed in the measured mass spectrum in each individual scan, so mass spectra recorded across the entire width of the peak are averaged together to create a mass spectrum that contains more accurate ion intensities. To ease the burden, the mass analyser can be forced to scan faster and faster, but eventually

a fundamental hardware constraint limits the scan speed. Faced with these limits, the analyst can narrow the mass range across which the analyser must scan, or choose to monitor only certain significant ions from within the mass range. In either case, the analyst risks losing the ability to accurately identify unexpected compounds in a complex mixture.

The discussion that follows is software-independent. Each computer system will handle the operations described in its own unique fashion, and there may be specialized procedures beyond those that are described here. It is expected that the analyst will understand the general principles involved, and then take the time to explicitly explore these functions on the particular instrument to be used for analysis.

Background subtraction Resolution in chromatography is established by the time between adjacent peaks in which no sample components are eluting into the source of the mass spectrometer. Generally, the higher the chromatographic resolution, the more ‘empty’ space there is in the chromatogram. The mass spectrometer is recording mass spectral data even during the times when nothing is eluting from the chromatograph. These scans become the mass spectra of the background. The background mass spectrum is not constant. During a GC-MS run the background changes because of increased bleed from the column at increased temperatures encountered during a temperature ramp, low-level, highly retained components, and the continual desorption of organic compounds and contaminants absorbed throughout the system. As background is not constant, the details of background subtraction are not constant, although the correct procedure is generally accepted.

There is no error-free method of arbitrarily reducing the contributions of background in a mass spectrum to zero. However, based on the assumption that the sample background and ionization is independent of the elution and ionization of the sample component itself, then the number of scans averaged together to create a background mass spectrum should be equal to the number of scans averaged together to provide the mass spectrum of the sample. Simplistically, if ten mass spectral scans are necessary to completely characterize a peak, and these ten scans will be averaged together, then the ‘background’ mass spectrum should also be the average of ten scans. The scans taken for the background should be taken from as close before the peak elution, and from as close after the peak elution, as practical. There is no guarantee that the intensities of background ions in the mass spectrum will be reduced to zero, but they

will be minimized relative to those ions that are derived from the sample component. Simple mathematical subtraction may lead to negative relative intensities for some ions; these are arbitrarily set to zero.

When two sample components elute very close to one another, it is not possible to follow the before/after procedure just outlined. In the simple identification of a background mass spectrum, advantage is taken of the fact that the background does not change rapidly. The portion of the chromatogram from which the background mass spectrum is taken is simply the first encountered as one moves to a point in the chromatogram when it is assumed that there is no contribution from the eluting compound. A more enlightened use of background subtraction involves creating a high quality mass spectrum from each of two closely eluting or even overlapped components. In this case advantage is taken of the fact that peak intensities that are reduced in intensity to zero do not distort the mass spectrum, and that the probabilities that ion masses overlap are small. In the case described, one can enter as background mass spectra those scans that are clearly from the second of two components with the assurance that the ions from this component will be effectively removed from the mass spectrum of the first.

The intensity behaviours of ions that belong to the background and those that belong to an eluting peak are different. This difference can be highlighted mathematically. The first derivative of the values for ion intensities that are changing will have a nonzero value. However, the first derivative of the ion intensities in an eluting peak will be characteristic in crossing zero at the retention time. This difference in behaviour can be used to identify ions from the sample as opposed to ions from the background. The mathematical result is an 'enhanced' mass spectrum. Note that the first derivatives for different ions will cross zero at slightly different times, depending on the rate of scan of the mass analyser.

Data averaging In the perfect chromatographic separation, the peak has a Gaussian shape. In the perfect spectroscopic detection system, the signal can thus be plotted as a convoluted function of mass analyser scan time and the number of scans across the peak profile, and the assumed constant level of noise recorded in the mass spectrum, from either chemical or electronic sources. None of these ideal assumptions is true. To increase the signal-to-noise (S/N) ratio of the mass spectrum recorded for a chromatographic peak, it is common practice, as described, to sum or average all of the mass spectra gathered as the peak elutes.

The need for data averaging is most apparent when the scan time is a significant fraction of the peak

width. Given that ten scans across a peak are needed to establish the elution profile, the example described here is for just such a situation. Further, we will make the assumption that (as is commonly the case) the analyser scan is from high mass to low mass. The first scans across a peak are recorded as the concentration of the sample in the source is increasing. There is a bias in ion intensities towards the low-mass end of the mass spectrum. If a steady state sample concentration is reached, a mass spectrum with accurate and true ion intensities is recorded. However, such a situation is unlikely. After the instantaneous maximum in sample concentration is reached, the amount of sample in the source starts to decrease, and the remaining scans are recorded as the concentration of the sample is decreasing. The trailing scans will also be biased in that the ion intensities at the higher mass end of the spectrum will be too high relative to their low-mass counterparts. If the peak is symmetrical, and there are enough scans on either side of the peak maximum, the bias can be muted by simply averaging all the spectra together. This processed mass spectrum should be approximately the same as if the sample concentration in the source was constant, and it can therefore be searched against a mass spectral library.

Intuitively, the analyst wants to average all the mass spectra that are recorded for an eluting peak, even at the leading and trailing edges of the peak where the signal is first and last discernible against background. Even though a simple summation is the most common practice, it is not optimal in terms of providing the maximum S/N ratio in the processed mass spectrum. Recent work by Chang shows that only the mass spectra for which the ions are at least 38% of the maximum recorded ion abundance should be included in the summation. Furthermore, the use of a matched filter (such as used in NMR experiments) provides an additional increment in S/N ratio, provided that the shape of the matched filter parallels that of the chromatographic peak itself. The data processing applies to any combination of chromatography and detection, but is demonstrated specifically with the combination of LC and MS. The widespread use of processed mass spectrometric data to provide enhanced chromatographic resolution, based on the independence of the mass spectrometric data, makes this study particularly worthwhile. It is revealing that background subtraction has been used in mass spectral data processing for decades, and essential elements of its character are still being deduced.

Reconstructed ion chromatograms A peak eluting from a chromatographic column exhibits a characteristic retention time. When using MS as a detection

technique, that retention time is determined by the point at which all the ion intensities in the mass spectrum reach their maximum value. As described previously, the first derivative of the ion intensities crosses zero. That statement was carefully crafted to differ from the statement that the retention time is the point at which the total ion current (TIC) trace reaches a maximum. The TIC summed intensity is derived from both sample-related and background ions. The two statements are usually, but not always, identical in meaning. Using the more accurate description also provides the underlying basis for introduction of the reconstructed ion chromatogram (RIC) procedure.

A data file contains mass spectra recorded as a function of time; the mass spectrum is a table of m/z values and intensities. Therefore the data file is a collection of intensities of all of the m/z channels recorded as a function of time. Any m/z value can be specified, and the intensity data can be extracted from the data set and plotted as a function of time. In the elution of a sample peak from a column into the mass spectrometer, all of the sample-related ions should follow a similar time profile as the concentration rises. It is assumed that if an ion properly 'belongs' in the mass spectrum, then its intensity profile should track in time all of the other sample-related ions. Therefore, the converse should hold. If an ion intensity trace follows the same profile as ions that are known to be in the mass spectrum, then it 'belongs' in the mass spectrum. More powerfully, if it does not follow that trace exactly, then it does not belong. The RIC is nothing but an independent series of intensity versus time traces that graphically establish spectral propriety, and provide hints when something is amiss. The plots are independently calculated, and the absolute intensity of the ion is normalized. The graphical appearance of correctness is striking in the alignment of peak maxima and in the duplication of peak shape on both leading and trailing edges. When there is an unresolved peak component, ions that belong in that mass spectra show a strikingly different trace. A peak that belongs in the background will show a slowly changing trace with multiple maxima.

If the sample analysed by GC-MS is a mixture of closely related compounds, the mass spectra of each member of that compound class will generally contain characteristic ions of the same mass. As the analyst recognizes that a correspondence exists between the ion mass and the compound class, the entire data set can be interrogated for those characteristic ions. The RIC trace should exhibit multiple maxima that correspond to the retention times of each of the individual compounds in that class. The

relative areas or peak heights for each trace do not directly represent the quantitative distribution of those class members, since they reflect the relative intensity of that mass-specific ion in the mass spectrum. However, the power of the RIC in highlighting compounds within a homologous series is evident.

Selected ion monitoring Selected ion monitoring (SIM) is a procedure used in data acquisition and processing in which the mass analyser is not scanned over a mass range, but instead hops rapidly between several preselected m/z values (this is called peak hopping). For example, instead of scanning the mass range from 35 to 1000 Da in 0.2 s, the analyser will spend some time at m/z 77, some time at m/z 91, some time on the ion at m/z 135, and finally some time at m/z 180. Usually, all of these ions are those that belong in the mass spectrum of the targeted sample component. In the scanning experiment the analyser will spend $0.2 \text{ s}/965 = 2.07 \times 10^{-4} \text{ s}$ recording the signal in each nominal mass channel. In the SIM experiment the same 0.2 s (ignoring the short time that it takes to hop between peaks) is spent monitoring the ion signal in four ion channels. The detector is integrating a signal for a period that is 242 times as long in the SIM experiment. If this is indeed where the signal is to be found, then an increase in the sensitivity of the mass spectrometric analysis can be attained simply by virtue of the fact that a longer time is spent recording the signal. S/N ratios for each individual ion trace are appropriately increased as well, since this value scales with the number of independent measurements taken. Various values for the increase in sensitivity attained with the use of SIM are found in the literature. These values range from 10 to 100 fold, and depend on the width of the ion mass window monitored, and the intensity of the ions to be found within that window. Unfortunately, ions chosen for SIM are often only those that are found in the mass spectrum of the targeted sample component. It is wise to include in the selected ions a m/z value that represents a nonsample ion, so that the true S/N ratio for the experiment can be determined.

The analyst should be clear about what is gained and what is lost in the SIM experiment. Clearly there is a gain in sensitivity. The resolution of the mass analysis is not changed, so there is no tradeoff here. What is lost is the generality of the mass spectrometric detection. In short, the analyst must already know the identity of the target compound, for example, and the masses of the ions to be monitored. These are established in separate experiments that precede the selection of the SIM experiment. If a large amount of an unexpected sample is eluted from the GC during the SIM experiment, and this unexpected

adulterant does not produce ions at the monitored masses, and there is no matrix effect as a result of its presence, it will simply go undetected, even if it elutes at exactly the same time as the targeted component. Loss of such 'insurance' capability should always be carefully considered when setting up a SIM protocol.

The output of a RIC looks identical to the output of a SIM experiment. However, in this case the RIC graphical output is the result of a data processing routine. During the data acquisition process, the mass analyser is scanned across the full mass range, and each scan is a complete mass spectrum in the stored computer file. A full data set can be interrogated repeatedly with different selected ions. A SIM experiment contains ion intensities only for those ions that were selected. The RIC provides an increase in confidence of spectral propriety, but no increase in sensitivity.

Advanced computer processing The combination of chromatography with MS would not exist today were it not for the capabilities of computers in instrument control, data acquisition, data processing, and spectral manipulation and display. Advances in computer capabilities have provided more precise control, faster and more accurate data acquisition, faster and more sophisticated data processing, and higher content and more striking visual displays of chromatographic and mass spectral data. Computational power has always been applied to the interpretation of mass spectral data, and computer-assisted interpretation of mass spectral data, specifically in the area of structure/spectral relationships, continues. Computer-aided interpretation, originally applied exclusively to EI mass spectra, is now used with success in the interpretation of CI, ESI, and MS-MS data. It is analytically compelling to support this expansion, as it is unlikely that libraries of these types of mass spectral data will grow to the size of the current libraries of EI mass spectral data. The precepts behind computer applications in the interpretation of mass spectral data have been described (Karjalainen). More recent applications have increased the speed and expanded the scope of applications, but no matter what, the progress the fundamental principles continue to apply. Pattern recognition programs can be used to recognize similarities in groups of mass spectra data. Calibration, especially in isotope ratio measurements, often involves sophisticated computer-performed mathematical algorithms. Pyrolysis MS often involves searches for similarities and differences in complex mass spectra through computer algorithms. Correlation analysis is used in many different areas of MS.

The growth in computer-assisted evaluation of chromatography-mass spectrometry data has been slower. This is surprising given the sophistication of computer hardware and software, and the proliferation of chromatography-mass spectrometry instruments. The quantitative information content of GC-MS has been described using latent variables in the context of multivariate analysis. Regression and least squares methods have been used to specifically model quantitative results obtained for GC-MS of closely eluting compounds. Procrustes analyses have been used to determine the number of significant masses in GC-MS, where significant masses represent the ions in the mass spectrum that differentiate one compound from the other. Each of these recent studies suggests that there is more information to be obtained from GC-MS than we have yet mined. The promise is that the general informational methods described will be adopted seamlessly into LC-MS and CE-MS as well.

Data Storage in Chromatography-Mass Spectrometry

Regulatory issues and requirements for good laboratory practice affect all users of analytical methods such as chromatography-mass spectrometry. Details and procedures for each user, company, or institution become part of the proper way of conducting scientific business for that organization, defined by tradition and regulation. Here, the causes and impacts of several overarching data storage and archiving issues are discussed. GC-MS is again used as the example, but of course the general issues apply to any form of chromatography-mass spectrometry.

The product of a GC-MS analysis is data. There is no collection of vials that represents a collection of compounds separated from a complex mixture. The sample aliquot analysed by the instrument is destroyed, leaving only measurement data as residue. Often, only a small fraction of that data appears in hard copy form for perusal by the analyst, who may receive a paper copy of a TIC trace, print-outs of a few selected mass spectra, and tabulated results of an automatic library search for each of these mass spectra. Each of these outputs is calculated as needed from the original data set, which is preserved within the data system, along with relevant parameters of instrument operation, calibration, and certification. Often there are several layers of safeguards that prevent post-analysis changes to the original data set. Further, in some instances a duplicate copy of the master data set is recorded remotely, while all post-run processing occurs from a local copy of the data. The backup of the data occurs automatically without

operator intervention. The rapid growth of GC-MS, coupled with the more rapid growth of regulation, implies that the sheer volume of this form of data will predictably overwhelm attempts to logically archive or access it.

Hardware Overview

GC-MS could not have been developed without the advent of the computerized data system. Conversely, the computerized data system makes it possible to exploit all the synergistic powers of the hyphenated method. It is revealing to return to early published forays into the method and read the concerns of the practitioners regarding the sheer volume of data that was available and recorded. In retrospect, the first data systems were primitive beasts. Processing speeds were very slow, and they were matched by the speed of the analogue-to-digital conversions. Data storage initially used magnetic tapes, similar to those still available today but with lower capacities. The early high-capacity data storage devices were removable platter drives. Generically, they were known as Winchester drives. The term Winchester comes from an early type of disk drive developed by IBM in 1973 that stored 30 MB and had a 30 ms access time. It was called a Winchester in honour of the 0.30-calibre rifle of the same name. For the mainframe data systems that controlled mass spectrometers, the platters (encased in cassettes with diameters of about 40 cm and thicknesses of about 5 cm) had a capacity of 10 MB. In GC-MS each platter filled up quickly; the full disk was removed from the drive, and an empty platter inserted. Winchester hard disk drives were not available for personal computers (PCs) until 1980. The PCs of today are more powerful than the mainframes used in the early days of GC-MS. Commercial systems are controlled by PCs, which is one reason that they have dropped in price. Storage capacities of 20 GBs on a single platter are available today.

Data records have a much longer life than does the original sample itself. There are rules that govern how long a sample or sample extract can be stored, at what temperature, and in what form. Outside of that time limit, that sample cannot be used for analysis. These rules exist as a result of concerns about sample degradation. In general, analysts do not worry about data degradation, although the long-term stability of magnetic-based recording media has been a topic of discussion. The relevant lifetime of data records depends on the availability of a software system that can access and manipulate the data. Analogies with commonplace computer software can be drawn readily, as each new iteration of software makes obsolete some fraction of the installed software base and its associated data. The problem is exacerbated by

a competitive marketplace and manufacturers that disappear or are eager to make older systems obsolete.

Data processing and manipulation routines are manufacturer-specific and sometimes proprietary. The computer for a mass spectrometer may remain in the laboratory past the time when the mass spectrometer itself is removed so that the system can be used as required to read and process old data files. Clearly this is neither a desirable nor an efficient approach to data archival management. Manufacturers of commercial mass spectrometers have become much more cognizant of this fact over the past few years, and analytical data interchange efforts have been undertaken. The issue of backwards data compatibility is significant, and should be considered as part of the yearly performance assessment of an analytical laboratory using chromatography-mass spectrometry. Hardware capabilities are not the only issue. The preferences and habits of individual analysts also affect the manner in which data are presented and interpreted. Individuals are shuttled into and out of laboratories regularly, and a record of individual proclivities needs to be maintained and understood, especially in systems as complex as chromatography-mass spectrometry. The proper time to determine whether archived data can be located, read, processed and re-evaluated is not in the midst of crisis or urgency. If the data are worth saving, it is worth going through an exercise to test one's ability to retrieve those data. If the exercise shows that retrieval and reuse is not feasible, the data should not be saved. Previously the criterion for saving the data was the amount of storage capacity that was available, as GC-MS files were 'large', and it was considered impossible to physically save all of the data that could be recorded. The files are still indeed 'large', but storage capacities have increased by a factor of 1000 over the past 20 years, while the files have increased in size by only a factor of 2-3 (the laboratory time frame has not changed in its perception, and the resolution of the recorded data has increased only slightly). Storage capacity is no longer a relevant issue. Meaningful retrieval has become the determinant factor.

Regulatory and Legal Issues

The very public disputations over drug testing of athletes is emblematic of many of the same issues that arise in defining and documenting the impact of chromatography-mass spectrometry. GC-MS, LC-MS, and CE-MS underlie analytical results in environmental testing, drug testing, pharmaceutical analysis, and forensic investigations, in addition to being core techniques in exploratory and discovery

research. Laboratory accreditation requires strict adherence to issues of sample handling, instrument calibration and operation, and data processing and archiving. Many commercial laboratories offer such services. This section touches on the broad perspectives of the field in this area.

It is important to remember that many analyses involving chromatography-mass spectrometry are protocol-driven. This means that the exact procedures and the instrumental means of analysis are prescribed in specific detail. Deviation results in an invalidation of the results. Such protocols may not represent the 'best' way of performing the analysis. Quality attributes such as fastest, cheapest, most sensitive, most accurate, or least prone to interference are comparative. Analytical laboratories are usually paid to produce results, not to provide comparisons. Regulations are prescriptive of what methodology can be used and proscriptive of anything else. Regulations most certainly lag behind state-of-the-art capabilities. A general rule is that regulations will not change until the approved methodology lags behind current methodology by a factor of 10. Further, that factor of 10 must be meaningful. A 10-fold lowering in the limit of detection is irrelevant if the current limit of detection suffices for practical needs.

The variability in legal treatment of analytical data from court-to-court and country-to-country suggests that any justification for preemptive consistency is weak. A chromatography-mass spectrometry approach generally recognized as valid by experts is a good basis on which to build an argument, and the 'value imputed by scientific consensus' argument is accepted in many legal systems. Analytical details have to be in conformance, and good laboratory practice helps to ensure this. In the final analysis, an explanation of the results of an analysis by chromatography-mass spectrometry will be presented to a jury or a judge with a minimum of scientific background. Here, clear and focused explanations of the basic principles of the analyses are of highest value; such explanations are the purpose of this overview.

Conclusions

It is dangerous to predict that all of the essential technical innovations that allow the linkage between chromatography and mass spectrometry are in place. It would be equally foolish to try and identify any combination for which the interface technology has not already been demonstrated, at least in a primitive sense. Certainly one major area of future innovation will be in the continued reduction in the size of the instruments. However, although gas chromato-

graphic and capillary electrophoretic separations on a chip level have been demonstrated, such devices have not swamped the marketplace. There is a realistic laboratory scale for the physical dimensions of instrumentation, and the sizes of a computer keyboard and a computer monitor are quintessential examples of that scale. Further reductions in physical size may be possible, but are not in concordance with human operation. It is not unrealistic to predict that GC-MS units will soon be the size of a PC, and may be moved about and reconfigured as easily. This reduction in physical size by a factor of about two from present day instruments will require clever packaging and insightful engineering, but does not depend on the development of fundamentally new technologies. As long as the analysis of samples occurs in a single instrumental channel (serial analysis), such scale is appropriate.

What would happen if mass spectrometers could be reduced in physical scale to the chip size (xyz dimensions of a few centimetres) and interfaced to some form of miniaturized chromatographic separation? Assuming that the performance of each individual combination was the same, the serial analysis has the potential to become a parallel analysis. The analytical results would be the same no matter which channel of analytical instrumentation is specified. Therefore parallel analysis allows many similar analyses to be run simultaneously, with special data acquisition and processing programs designed to zero identical results (results identical to each other or to a standard result) and highlight differences. Alternatively, adjacent channels of analysis may sample a system in which a variable (temperature, pressure, time, light, reactant concentration) is systematically varied. The possibilities for such miniature analytical instrument arrays are diverse and exciting.

What technological impediments stand between the present and, as an example, miniaturized laser ionization, time-of-flight mass spectrometers? The ions themselves are small, lasers and filaments can be small, and flight tubes are nothing but channels that can be folded into compressed S shapes. Electron multiplier detectors can also be made very small, subject only to space charge effects that limit the entire system. Electrical connections to the outside world are entirely manageable on a micrometre scale. There are two other physical connections to the outside world that have to be managed. The first is the introduction of the sample to the mass spectrometer. Assuming that the sample is eluted from the column, the problem is transformed into loading the sample onto the column. Miniaturized robotic injectors or microfluidics are already available for this task. The second physical connection is the attainment and

maintenance of a vacuum. Vacuum pumps are, in general, not amenable to miniaturization, since they must possess the physical means to transport molecules from inside the system to the outside environment. The only restriction is the insistence on maintaining vacuum, with the assumption that many samples will be analysed by the same mass spectrometer. If a miniaturized mass spectrometer has a total evacuated volume of 1 mL (not outside the reasonable scale), then a vacuum reservoir of 100 mL suffices for pumping by virtue of expansion. Essentially the vacuum is a rechargeable resource. Removing of the vacuum hardware as a physical limitation to the size of the mass spectrometer will be a genuine innovation in the field. Hopefully, this same overview written ten years from now will document the applications of new miniaturized chromatography-mass spectrometry systems.

MEMBRANE SEPARATION

R. W. Baker, Membrane Technology & Research Inc. (MTR), Menlo Park, CA, USA

Copyright © 2000 Academic Press

Introduction

Since the 1970s industrial membrane separation technology has developed into a US\$1–2 billion per year business. The market is fragmented, but can be divided into six principal industrial process areas: microfiltration, ultrafiltration, reverse osmosis, electrodialysis, gas separation and pervaporation. Dialysis, another membrane separation technique, is limited to two biomedical processes, haemodialysis (artificial kidneys) and blood oxygenators (artificial lungs). The market for these two biomedical applications is another US\$2 × 10⁹ per year. Further membrane separation applications, including membrane contactors, membrane reactors and coupled and facilitated transport, are under development. Although

similar membranes and membrane module designs are used in all of these process areas, the ways by which the separations are performed and the process applications are very different. A brief overview of each process is given here; more detailed descriptions of the individual processes are given elsewhere in the encyclopedia.

History

The concept of the ideal semipermeable membrane able to separate two species with the theoretical minimum work has been used by thermodynamicists for more than 150 years, but attempts to use membranes for practical separations did not begin until the 1900s, when Bechhold devised a technique for preparing nitrocellulose membranes of graded pore size. Later workers, particularly Zsigmondy, Bachmann, Elford and Ferry, refined these preparative techniques and membranes were used to separate a variety of laboratory solutions by dialysis and microfiltration.

By the 1930s, microporous membranes were produced commercially on a small scale. The first ion exchange membranes were made at about the same time; these were used by Teorell, Meyer and Seivers to develop their theory of ion transport. This work led eventually to the development of electrodialysis.

By the 1960s, therefore, the elements of modern membrane science had been developed, but membranes were only used in laboratories and in a few small, specialized industrial applications. There was no significant membrane industry, and total sales for all applications probably did not exceed US\$10 million. Membrane processes suffered from three problems that prohibited their widespread use: they were too slow, too expensive and too unselective. Partial solutions to each of these problems have since been developed, and sales of membranes and membrane separation equipment have grown several hundred-fold. Currently, several tens of millions of square metres of membranes are produced each year, and a membrane industry has been created.

The problem of slow permeation rates through membranes was largely overcome in the late 1960s and early 1970s by the development of imperfection-free ultrathin membranes. These membranes are anisotropic structures and consist of a thin selective surface film supported by a much thicker microporous substrate to provide mechanical strength. Because the selective surface film is very thin, these membranes have high fluxes.

The problem of packing a large membrane area into a low-cost module has also been solved since the 1980s. The earliest module designs were plate-and-frame or tubular units similar to conventional heat exchangers. These designs are still used in some processes, such as ultrafiltration, in which the ability to clean fouling deposits from the membrane surface is important. However, the cost of both designs is relatively high, and in most processes they have been displaced by capillary, hollow-fine-fibre and spiral-wound module designs.

The problem of low selectivity remains one of the principal limitations of membrane processes. No general solution has been found, although substantial improvements have been made since the 1950s.

Ultrathin Membranes

The first useful ultrathin membranes were cellulose acetate reverse osmosis membranes produced by Loeb and Sourirajan, two researchers at the University of California at Los Angeles. The development of these thin, and hence high flux, membranes led to the reverse osmosis industry in the 1960s. In the Loeb–Sourirajan technique, a solution containing ap-

proximately 20% polymer is cast as a thin film on a nonwoven fabric web and is then precipitated by immersion in a bath of water. The water very rapidly precipitates the top surface of the cast film, forming the selective skin. This skin then slows down the entry of water into the underlying polymer solution, which precipitates much more slowly, forming a more porous substructure. A scanning electron micrograph showing the porous substructure and the selective skin of a Loeb–Sourirajan membrane is shown in **Figure 1**. The selective layer thickness is typically less than 0.2 μm .

About one-third of the reverse osmosis and almost all ultrafiltration membranes currently produced are made by the Loeb–Sourirajan technique. This type of membrane is also widely used in gas separation processes.

In recent years, new approaches have been developed to produce anisotropic membranes with even thinner selective layers than those made by the Loeb–Sourirajan method. Selective layers only a few tens of nanometers in thickness, and effectively free of imperfections, have been claimed for these so-called thin-film composite membranes. Thin-film composite membranes can be made by a number of methods, of which two are particularly important: coating with a dilute polymer solution and interfacial polymerization. In the coating method, which was developed first, a very dilute solution of the polymer is prepared in a volatile solvent, such as hexane. A thin film of this polymer solution is deposited on the microporous support surface by immersing and then slowly withdrawing the support from the solution. As the solvent evaporates, an extremely thin polymer film is left behind. This technique is used to manufacture ultrathin membranes for gas separation and pervaporation.

The second important method for preparing composite membranes is interfacial polymerization. In this method, an aqueous solution of a reactive monomer, such as a diamine, is deposited in the pores of a microporous support membrane. The membrane is then immersed in a water-immiscible solvent solution containing a multivalent reactant, such as a triacid chloride in hexane, which causes the monomer to polymerize and cross-link. Polymerization is confined to the interface of the two immiscible solutions, so a thin, highly selective layer is formed. The procedure is illustrated in **Figure 2**. The interfacial polymerization technique is used to produce most of today's reverse osmosis membranes.

Membrane Modules

The principal module designs – plate-and-frame, tubular, hollow-fibre and spiral-wound – are illustrated

Figure 1 Scanning electron micrograph of the cross-section of a Loeb-Sourirajan reverse osmosis membrane. The development of this type of anisotropic membrane was a critical breakthrough in the development of membrane technology.

Figure 2 Preparation of ultrathin composite membranes by reaction of an amine dissolved in water and an acid chloride dissolved in hexane. The chemistry shown is widely used to prepare seawater desalination reverse osmosis membranes. (Reproduced with permission from Roselle LT *et al.* (1977). In: Sourirajan (ed.) *Reverse Osmosis and Synthetic Membranes*.)

in Figures 3 and 4. In the plate-and-frame design shown in Figure 3A a series of membrane discs separated by spacers and support plates are held between two end plates connected by a tension rod. The geometry of the plates is such that solution entering one end of the module passes sequentially over all the membrane area. Solution that permeates the membrane is collected in a permeate collection channel. Tubular modules shown in Figure 3B consist of a porous support tube, which is coated on the inside surface with the selective membrane. The porous support tube nests inside steel or strong plastic tubes that

can support the applied pressure. Each tube is between 0.5 and 2 cm in diameter and up to five tubes can be housed in a single support tube. Tubular modules are now only used in ultrafiltration applications for which good flow distribution across the membrane surface with no stagnant areas is required to control membrane fouling. In this application up to 20 tubes are connected in series as shown in Figure 3B.

Plate-and-frame and tubular membranes were widely used in the early days of the modern membrane era, but by the 1980s had been largely displaced by hollow-fibre, capillary or spiral-wound membrane

(A) Plate-and-frame module

(B) Tubular module

(B) Spiral-wound module

Spiral-wound module cross-section

Figure 4 Schematic illustrating hollow-fibre (A) and spiral-wound (B) membrane modules. Most large-scale membrane processes use one of the designs shown.

modules, which are much less expensive to produce per square metre of membrane area. Capillary and hollow-fine-fibre membranes are quite similar, differing principally in the diameter of the fibre used. Both types are produced by a spinning process much like conventional fibre spinning. As a result, the cost of producing the membrane per square metre is quite low. Most of the cost of producing hollow-fibres is incurred in the fibre potting operation when fibres are mounted inside the module shell. Currently, in capillary modules, the feed fluid circulates through the fibre lumen (bore side) as shown in Figure 4A. In hollow-fibre modules, the feed fluid circulates around the outer surface (shell side) of the fibres as shown in Figure 4B.

Spiral-wound modules were originally developed for reverse osmosis applications but are now used in ultrafiltration and gas separation processes as well. This work, carried out by Fluid Systems Inc. under sponsorship of the Office of Saline Water

(later the Office of Water Research and Technology), resulted in a number of spiral-wound module designs. The design shown in Figure 4 is the most common, consisting of a membrane envelope wound around a perforated central collection tube. The module is placed inside a pressure vessel, and feed solution is circulated axially down the module across the membrane envelope. A portion of the feed permeates into the membrane envelope, spirals towards the centre of the module and exits through the collection tube.

The flat-sheet membranes used in spiral-wound modules usually have higher fluxes than capillary and hollow-fibre membranes made from the same material. This is because it is difficult to make hollow-fibre selective skins as thin as flat-sheet skins. For this reason, although spiral-wound modules are usually two to five times more expensive on a square metre basis than hollow-fibre membranes, they are competitive in many applications.

Membrane Selectivity

Improving membrane selectivity is still an area of active research. In some applications such as desalination of water, progress has been made, and membranes have the required selectivity to compete with other processes such as distillation. The first reverse osmosis membranes had salt rejections of approximately 96–97% and could only produce potable water from low concentration brackish water feeds. The best current membranes have salt rejections of up to 99.7% and can produce potable water from seawater. Further improvements in membrane selectivity are not required in this application.

In other applications, the low selectivity of membranes remains a problem. Ultrafiltration membranes, for example, cannot separate dissolved macromolecules, such as albumin (M_r 60 000) and γ -globulin (M_r 150 000). Therefore, ultrafiltration is limited to the separation of very large molecules from very small ones, such as macromolecules from dissolved micro-ions. Selectivity problems also exist in electrodialysis, gas separation and pervaporation.

Mechanism of Membrane Separation

The property of membranes used in separation processes is their ability to control the permeation of different species. Most membranes fall into one of the two broad categories illustrated in **Figure 5**. In microporous membranes, permeants are separated by pressure-driven flow through tiny pores. A separation is achieved between different permeants because one of the permeants is excluded (filtered) from some of the pores through which the smaller permeants move. In solution-diffusion membranes the membrane material is a dense polymer layer and contains no fixed pores. Permeants dissolve in the membrane material as in a liquid and then diffuse through the membrane down a concentration gradient. Separation of different permeants oc-

curs because of differences in the solubility of the permeant in the membrane material and the rate at which the permeant diffuses through the membrane.

The difference between the pore-flow and the solution-diffusion mechanisms lies in the relative size and lifetime of pores in the membrane. In dense polymeric solution-diffusion membranes, no permanent pores exist. However, tiny free volume elements, a few tenths of a nanometre in diameter, exist between the polymer chains from which the membrane is made. These free-volume elements are present as statistical fluctuations that appear and disappear on a timescale only slightly slower than the motion of molecules traversing the membrane. Permeating molecules diffuse from free-volume element to free-volume element at a rate determined by the thermal motion of the polymer chains from which the membrane is made. In contrast, in a pore-flow membrane the pores are fixed and do not fluctuate in position or size on the timescale of molecular motion. The larger the individual free-volume elements are, the more likely they are to be present long enough to produce pore-flow characteristics in the membrane. As a rule of thumb the transition between permanent (pore-flow) and transient (solution-diffusion) pores appears to be in the range 0.5–1.0 nm diameter. This means that the processes of gas separation, reverse osmosis and pervaporation, all of which involve separation of permeants with molecular weights of less than 200, use solution-diffusion membranes. On the other hand, microfiltration and ultrafiltration, which involve separation of macromolecular or colloidal material, use finely microporous pore-flow membranes.

Commercial Membrane Separation Processes

The current status of membrane separation technology is summarized in **Table 1**. There are seven commercial membrane separation processes. Of these, the first five – microfiltration, ultrafiltration, reverse osmosis, electrodialysis and dialysis – are all well-established technologies with a market served by several experienced companies. Although incremental improvements in membranes and membrane systems for these technologies are expected, no major breakthroughs appear imminent. The remaining two technologies – gas separation and pervaporation – are developing technologies for which the market size, application area, and process design are still changing. Finally, several processes not shown in **Table 1**, including coupled and facilitated transport, membrane contactors and membrane reactors, are still in

Figure 5 Schematic illustrating the two principal types of membrane separation mechanisms. (A) Microporous membranes separate by molecular filtration. (B) Dense solution-diffusion membranes separate because of differences in the solubility and mobility of permeant in the membrane material.

Table 1 Summary of the established membrane separation technologies

<i>Process</i>	<i>Type of membrane</i>	<i>Material passed</i>	<i>Material retained</i>	<i>Driving force</i>	<i>Status – typical application</i>
Microfiltration	Finely microporous 0.1–10 μm	Water, dissolved solutes	Suspended solids, bacteria	Pressure difference 5–50 psi	Developed (\sim US\$700 million per year). Removal of suspended solids, bacteria in pharmaceutical, electronics industries
Ultrafiltration	Finely microporous 1–100 nm	Water, dissolved salts	Macromolecules, colloids	Pressure difference 20–100 psi	Developed (\sim US\$150 million per year). Removal of colloidal material from wastewater, food process streams
Reverse osmosis	Dense solution-diffusion	Water	Dissolved salts	Pressure difference 100–1000 psi	Developed (\sim US\$200 million per year). Drinking water from sea, brackish or groundwater; production of ultra-pure water for electronics and pharmaceutical industries
Electrodialysis	Electrically charged films	Water	Ions	Voltage difference 1–2 V	Developed (\sim US\$200 million per year). Drinking water from brackish water; some industrial applications too
Dialysis	Finely microporous 10–100 nm	Dissolved salts, dissolved gases	Blood	Concentration differences	Developed (\sim US\$1.3 billion per year for artificial kidney; US\$500 million per year for artificial lung)
Gas separation	Dense, solution-diffusion	Permeable gases and vapours	Impermeable gases and vapors	Pressure difference 100–1000 psi	Developing (\sim US\$150 million per year). Nitrogen from air, hydrogen from petrochemical/refinery vents, carbon dioxide from natural gas, propylene and VOCs from petrochemical vents
Pervaporation	Dense, solution-diffusion	Permeable micro-solutes and solvents	Impermeable micro-solutes and solvents	Vapour pressure 1–10 psi	Developing (\sim US\$10 million per year). Dehydration of solvents (especially ethanol)

the laboratory or early commercial stage. In the following sections each of these membrane technology areas is described briefly. More detailed descriptions of the more important processes are given elsewhere in the encyclopedia.

Microfiltration

The process Microfiltration, ultrafiltration and reverse osmosis are related membrane processes differing in the size of the material retained by the membrane. As shown in **Figure 6**, reverse osmosis membranes can generally separate dissolved micro-solutes with a molecular weight below 500 by a solution-diffusion mechanism. When the molecular weight of the solute exceeds 500, the separation mechanism of the membrane is molecular filtration, in which separation characteristics are determined by the size of the particles in the mixture and the diameter of the pores in the membrane. By convention, membranes having pore sizes up to approximately 0.1 μm in diameter are considered to be ultrafiltration membranes. Microfiltration membranes are those with pore diameters in the range of 0.1 to 10 μm .

Above 10 μm the separation medium is considered to be a conventional filter.

Ultrafiltration/microfiltration membranes fall into two broad categories: screen membrane and depth membrane filters, as shown in **Figure 7**. Screen filters are anisotropic with small surface pores on a more open substructure. The surface pores in screen membrane filters are uniform and show a sharp cutoff between material that is completely retained by the membrane and material that penetrates the membrane. Retained material accumulates on the membrane surface. Depth membrane filters have a much wider distribution of pore sizes and usually have a more diffuse cutoff than screen membrane filters. Very large particulates are retained on the surface of the membrane, but smaller particulates entering the membrane are trapped at constrictions or adsorbed onto the membrane surface. Screen filters are usually used in ultrafiltration applications (see next section). The membrane pores are normally very small, on the order of 5–50 nm in diameter. Particulates and colloidal matter retained at the membrane surface are removed by a tangential flow of the feed solution. In this type of process, 80–90 vol% of the

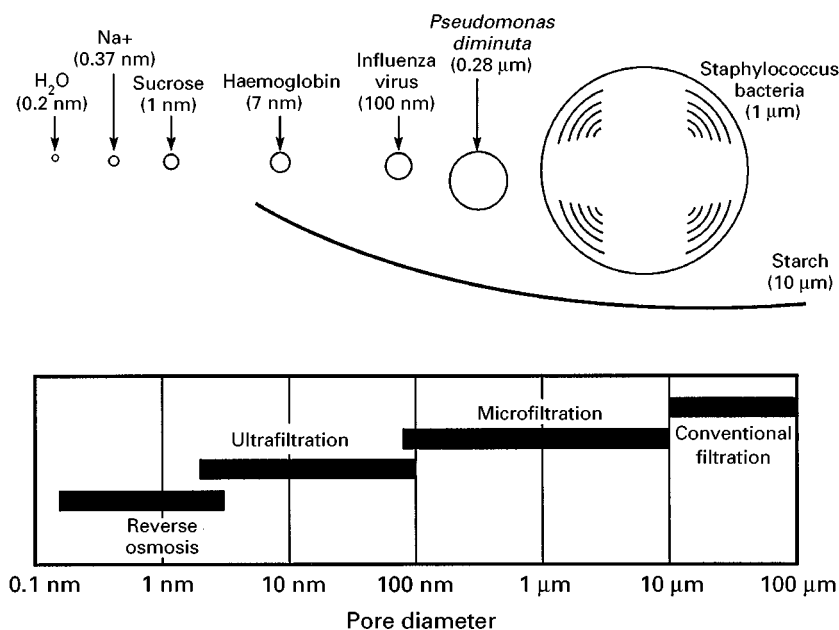

Figure 6 Pore sizes of reverse osmosis, ultrafiltration, microfiltration and conventional filtration membranes.

feed solution permeates the membrane as a clean filtrate. The remaining solution containing the rejected material is collected as a concentrated residue.

Depth filters are usually used in microfiltration applications. The surface membrane pores can be quite large, on the order of 1–10 μm in diameter, but many smaller restrictions occur in the interior of the membrane. This means that bacteria or virus particles as small as 0.2 μm in diameter are completely prevented from penetrating the membrane. Microfiltration membranes are usually used as an in-line filter. All of the feed solution is forced through the membrane by an applied pressure. Retained particles are collected on or in the membrane.

The lifetime of microfiltration membranes is often improved by using a more open prefilter membrane

directly before the final membrane. Prefilters are not absolute filters, but trap most of the very large particulates and many of the smaller ones before the feed solution reaches the finer membrane filter. This reduces the particle load that the finer membrane must handle, and thus increases its useful life.

Applications The primary market for microfiltration membranes is disposable cartridges for sterile filtration of water for the pharmaceutical industry and final point-of-use polishing of ultrapure water for the electronics industry. The cost of microfiltration compared with the value of the products is small. Cold sterilization of beer, wine and other beverages is another emerging market area. In these processes the microfiltration cartridge removes all yeast and

Figure 7 Separation of particulates can take place at the membrane surface according to a screen filtration mechanism (A) or in the interior of the membrane by a capture mechanism as in depth filtration (B).

bacteria from the filtrate. This process was introduced on a commercial scale in the 1960s. Although not generally accepted at that time, the process has become common in recent years.

Ultrafiltration

The process Ultrafiltration is intermediate between microfiltration and reverse osmosis. The most retentive ultrafiltration membrane has a substantial rejection to microsolute, such as raffinose (M_r 504), while the most open ultrafiltration membrane will be just able to retain a molecule of relative molecular mass one million. In practice, the distinction between ultrafiltration, reverse osmosis and microfiltration is vague, and it is possible to prepare membranes covering the entire range of reverse osmosis, ultrafiltration and microfiltration by making small changes in membrane preparation procedures.

Essentially all ultrafiltration membranes are screen filtration membranes and separate the retained material because of the small pores in their top surface layer (see Figure 7A). Membranes are characterized by their molecular weight cutoff, which is usually defined as the molecular weight at which the membrane retains more than 95% of the test solute. The definition is ambiguous, because flexible-backboned, linear molecules can penetrate membranes more easily than rigid, globular molecules, such as dissolved proteins. In addition, despite the claims of the manufacturers, no ultrafiltration membrane has a perfectly sharp molecular weight cutoff. All membranes contain a range of pore sizes and the passage of molecules through the pores is completely unhindered only for very small molecules. Typical molecular weight cutoff curves for a series of commercial membranes are shown in Figure 8.

Ultrafiltration systems generally operate at pressures of 20–100 psi (140–690 kPa). Osmotic pressure effects are not significant in ultrafiltration, and high operating pressures are not required to produce high fluxes. Moreover, because of their porous structure, ultrafiltration membranes compact under pressures above 100 psi (690 kPa).

The most important problem associated with ultrafiltration membranes is surface fouling. The problem is illustrated in Figure 9. Material unable to pass through the membrane accumulates at the surface, forming a solid gel-like film that acts as a barrier to the flow of permeate through the membrane. The thickness of the fouling film is controlled by the sweeping action of the feed solution past the membrane surface. This circulating flow of solution hydrodynamically scrubs the membrane surface, continuously removing the surface film. Thus a balance is

Figure 8 Molecular weight cutoff curves of various ultrafiltration membranes. (Amicon Corporation trade literature.)

achieved between circulation of solution past the membrane surface, which removes the gelled material, and the flux of permeate through the membrane, which brings fresh material to the membrane surface. Therefore, in ultrafiltration, only a portion of the feed

Figure 9 Schematic of ultrafiltration illustrating the dynamic process of deposition and removal of particulate and colloidal material from the surface of the membrane.

solution permeates the membrane; the remaining solution, containing the retained material, is removed as a concentrated residue stream.

If the feed solution circulation rate across the membrane surface is increased, the thickness of the fouling layer on the membrane surface decreases, and higher permeate fluxes through the membrane are obtained. However, at some point the increased energy cost involved in recirculating the feed solution offsets the savings produced by the higher membrane fluxes. With highly fouling solutions, energy consumption of 30–100 kWh per 1000 gallons (30–100 MJ m⁻³) of permeate produced is typical. The resulting electric energy expense represents a large fraction of the operating cost of an ultrafiltration plant. Increasing the operating pressure of the membrane system to force more permeate through the membrane is not a viable method of increasing the membrane flux because this only produces a thicker gel layer on the membrane surface so that the flux remains constant or even declines.

Even when most of the layer of deposited material on the membrane surface is continuously removed, a portion remains and gradually densifies. This results in decreased permeate flux through the membrane with time. Periodically, ultrafiltration membrane modules are cleaned by washing with a membrane-cleaning solution. This restores the flux to almost its original value, after which the flux begins to decline again. The process is illustrated in **Figure 10**. Unfortunately, cleaning of badly fouled membranes does not completely restore the flux to the starting value so that a proportion of the membrane flux is permanent-

ly lost. This permanent loss results from deposits of fouling material inside the membrane, which cannot be removed even by vigorous cleaning. The fouling material gradually accumulates until even the flux of a freshly cleaned membrane is less than 50% of the original value. At this time, the membrane is due for replacement. A typical ultrafiltration membrane life-time is 1–3 years.

Because of membrane fouling, the flux of ultrafiltration membranes depends highly on the composition of the feed solution and the process operating conditions. In the removal of trace particulates for the preparation of ultrapure water, the feed solution is already clean, and fluxes higher than 50–100 gal per ft² per day (85–170 L per m² per day) are achieved. With more concentrated and contaminated solutions, such as food processing streams, industrial wastewaters, or electrocoat paint wastes, typical fluxes are 10–30 gal per ft² per day (17–50 L per m² per day).

Applications Ultrafiltration membranes were originally developed for the laboratory market and found an application in the concentration and desalting of protein solutions. Later, Abcor and Romicon developed the industrial ultrafiltration market. The first major application was the ultrafiltration of electrocoat paint. The process is illustrated in **Figure 11**. In electrocoat paint operations metal parts are immersed in a tank containing 15–20% of the paint emulsion. After coating, the piece is removed from the tank and rinsed to remove excess paint. The ultrafiltration system removes ionic impurities from the paint tank carried over from earlier operations and provides clean rinse water for the countercurrent rinsing operation. The concentrated paint emulsion is recirculated back to the tank. Tubular and capillary fibre membrane modules are generally used in these plants because the feed solution easily fouls the membrane. Other large applications of ultrafiltration are the concentration of milk whey in the food industry to recover milk proteins and to remove lactose and salts in the membrane filtrate, and the concentration of oil emulsions in the metal finishing industry. Although some ultrafiltration plants treat industrial waste streams, this is not a common application because the process is expensive. The preparation of ultrapure water by ultrafiltration for the electronics industry is a newer, but growing, application. Biotechnology applications are, as yet, small.

The problem of membrane fouling in ultrafiltration systems requires expensive, energy-consuming pumps to recirculate the feed solution. Costs of ultrafiltration systems are on the order of US\$5–10 per 1000 gal of permeate, precluding its use in large, low-value applications such as wastewater treatment.

Figure 10 Ultrafiltration flux as a function of time for an electrocoat paint latex solution. Fouling causes flux decline in a matter of days. Periodic cleaning is required to maintain high fluxes.

Figure 11 Flow schematic of an electrocoat paint ultrafiltration system. The ultrafiltration system removes ionic impurities from the paint tank carried over from the chromate/phosphate cleaning steps and provides clean rinse water for the countercurrent rinsing operation.

Therefore, ultrafiltration is limited to the type of high-value streams listed above. Development of more fouling-resistant membranes and better module designs could allow wider use of the process.

Reverse Osmosis

The process The processes of osmosis and reverse osmosis are illustrated in **Figure 12**. In normal osmosis, a membrane is used to separate water from a salt solution. If the membrane is semipermeable, that is, it allows the passage of water but does not pass salt, the small difference in water concentration (salt solution) will cause water to flow into the salt side of the membrane. This flow will continue until the hydrostatic pressure head on the salt solution exactly balances the flow of water across the membrane. This balance is known as osmotic equilibrium. In reverse

osmosis, a pressure is applied to the salt solution that is even higher than the osmotic pressure of the solution. This applied pressure reverses the osmotic water flow, and water flows from the salt solution to the pure water side of the membrane. Therefore, reverse osmosis is a method of desalting saltwater solutions. Equilibrium osmotic pressures are directly proportional to salt concentration and are surprisingly large. For example, the osmotic pressure for sodium chloride is approximately 100 psi (690 kPa) for a 1% salt solution.

Two parameters affect the performance of reverse osmosis membranes. The first is the flux or flow per unit area per time, J , of water through the membrane, usually described by the equation:

$$J = A(\Delta P - \Delta \pi) \quad [1]$$

Figure 12 Osmotic effects across a semipermeable membrane. (Reprinted with permission from Roper and Lightfoot (1995) *Journal of Chromatography* 702: 3–26, with permission from Elsevier Science.)

where A is the hydrodynamic water permeability parameter, ΔP is the pressure difference across the membrane, and $\Delta\pi$ is the osmotic pressure difference across the membrane. Thus, once the osmotic pressure of the salt solution has been overcome, the water flux increases linearly with applied pressure. The salt flux through reverse osmosis membranes, J_s , is proportional to the salt concentration differences (ΔC) across the membrane, but is independent of the applied pressure. Thus:

$$J_s = B(\Delta C) \quad [2]$$

where B is the salt permeability factor. This means that the performance of reverse osmosis membranes, as measured by the salt rejection, improves as the applied pressure increases. Therefore, reverse osmosis membranes are usually operated at high pressures to obtain the maximum throughput commensurate with reasonable capital and energy costs. With current membranes, operating pressures are usually between 200 (1380) and 800 psi (5520 kPa).

The second parameter that affects membrane performance is the salt passage through the membrane. Ideally, the membrane should be completely selective for salt. This is never the case, and a small fraction of the salt passes through the membrane. The fraction that appears in the product is usually measured in terms of the rejection coefficient of the membrane, defined as:

$$R = \frac{[\text{salt concentration in feed} - \text{salt concentration in product}]}{\text{salt concentration in feed}} \times 100\% \quad [3]$$

Thus, a completely selective membrane has a rejection of 100%, whereas a completely nonselective membrane has a rejection of 0%. A typical plot of flux and rejection versus operating pressure is shown in Figure 13.

The first successful reverse osmosis membranes were made by Loeb and Sourirajan and had rejections in the range 97–98%. These membranes produced potable water (less than 500 ppm salt) from feed water containing up to 1% salt. This salt concentration is typical of many brackish groundwaters, so these membranes found an immediate application in the desalination of such waters. However, production of potable water from seawater requires a membrane with a salt rejection of greater than 99%. Loeb–Sourirajan cellulose acetate membranes can be modified to obtain this rejection, but only by reducing membrane flux to uneconomically low values. In the mid-1970s, Du Pont produced improved polyamide hollow-fibre membranes (the B10 Permeator) which had greater than 99% rejection. At about the same

Figure 13 Flux and rejection data for a model seawater solution (3.5% sodium chloride) in a good quality reverse osmosis membrane (FilmTec Corp. FT 30 membrane) as a function of pressure. The salt flux, in accordance with eqn [2], is essentially constant and independent of pressure. The water flux, in accordance with eqn [1], increases with pressure, and, at zero flux, meets the pressure axis at the osmotic pressure of seawater ~ 350 psi. (Reprinted from Wijmans JG and Baker RW (1995) The solution-diffusion model: a review. *Journal of Membrane Science* 107: 1–21, with permission of Elsevier Science.)

time, interfacial polymerization composite membranes were produced by Cadotte at North Star Research. These composite membranes had salt rejections greater than 99%, and subsequent improvements have raised these rejections to 99.5–99.8%. Interfacial composite membranes have now become the industry standard; three-quarters of current reverse osmosis membranes are of this type.

Reverse osmosis membranes are produced in several module configurations. Most of the modules used are of the spiral-wound type, which has 80% of the market. Hollow-fibre membrane modules are generally limited to seawater reverse osmosis plants. A few plate-and-frame and tubular modules are used in food processing and the treatment of industrial wastewater, which usually contain high levels of suspended solids and require this type of nonfouling module.

Applications Approximately half of the reverse osmosis systems currently installed are desalinating

brackish water or seawater. Another 40% are used to produce ultrapure water for electronics, pharmaceuticals and power generation. The remainder are used in small niche applications such as pollution control and food processing.

Brackish water desalination The salinity of brackish groundwater is usually between 1500 and 5000 mg L⁻¹. The World Health Organization recommends that drinking water should contain less than 500 mg L⁻¹ salt, so up to 90% of the salt must be removed from these waters. This is easily achieved by reverse osmosis. A typical process flow scheme is shown in **Figure 14**. Frequently brackish water is contaminated with suspended solids, so flocculation, sand filtration, and a final cartridge filter are used to remove these components first. Adjustment of pH and addition of antiscalants may also be necessary to prevent calcium, magnesium or silica precipitating on the membrane as water is removed and the feed becomes more concentrated. The water may also be sterilized by addition of chlorine to prevent bacterial growth on the membrane. Even when these elaborate and costly feed water pretreatment steps are used, some fouling of the membrane still occurs. Therefore, periodically the plant is taken off-line and the membranes are cleaned by circulating a hot cleaning solution. Typical operating pressures for these systems are in the 200–300 psig range. Plant capital costs are in the range US\$1.00–2.00 per gal per day (plant) capacity, and operating costs are about

US\$1–2 per 1000 gal of treated water produced. Well-maintained plants have useful membrane lifetimes of 3–5 years.

Seawater desalination Seawater contains about 3.5% dissolved salt, which means membranes with salt rejections above 99.3% are required to produce potable water. Today's membranes can easily meet these targets, and many seawater desalination plants are now operating. Because of the high osmotic pressure of seawater (~ 350 psi (2415 kPa)) these plants operate at pressures of 800–1000 psi (5520–6900 kPa). Typical seawater reverse osmosis plants have a capital cost of US\$4–5 gal per day capacity and produce desalted water for a cost of about US\$5 per 1000 gal of product. These costs mean the process is most competitive for systems below 10 million gal per day capacity. Above this range economies of scale tend to favour multi-effect evaporation plants often built to use the waste heat from electric power stations.

Ultrapure water With the development of the electronics industry, a large market has emerged for reverse osmosis plants to produce ultrapure water containing < 1 ppb total ions from water normally containing 50–100 ppm total ions. Typical operating pressures for the reverse osmosis systems used in these plants are low, on the order of 100–150 psi (690–1035 kPa). The reverse osmosis plant removes 98–99% of the salts and dissolved particles in the feed

Figure 14 Flow schematic of a brackish water reverse osmosis plant. The plant contains seven pressure vessels each containing six membrane modules. The pressure vessels are arranged in a Christmas tree array to maintain a high feed velocity through the modules as treated water is removed in the permeate.

water. Carbon adsorption and ion exchange units are used to remove the remaining contaminants.

Electrodialysis

The process Electrodialysis is a process in which electrically charged membranes are used to separate ions from aqueous solutions under the driving force of an electrical potential difference. The process, illustrated in **Figure 15**, utilizes an electrodialysis stack built on the filter press principle. The stack consists of 200–400 alternate cationic and anionic membranes between two electrodes; the aqueous feed solution flows through the cells between each pair of membranes. When an electrical potential difference is applied between the two electrodes, positively charged cations in the feed solution move toward the cathode. These ions easily pass through the negatively charged cation exchange membranes, but are retained by the positively charged anion exchange membranes. Similarly, negatively charged anions migrate towards the anode, pass through the anion exchange membrane and are retained by the cation exchange membrane. Because of the arrangement of ion-selective

membranes, the migrating ions become concentrated in each alternate cell in the stack. Thus, ions removed from the aqueous feed solution are concentrated into two separate streams.

Applications

Brackish water Brackish water desalination is the largest application of electrodialysis. The competitive technologies are ion exchange for very dilute solutions (below 500 ppm) and reverse osmosis for solutions above 2000 ppm salt. In the 500–2000 ppm range, electrodialysis is almost always the lowest cost process. One advantage of electrodialysis when applied to brackish water desalination is that a large fraction, typically 80–95% of the brackish feed, is recovered as potable water. However, these high recoveries mean that the concentrated brine stream produced is 5–20 times more concentrated than the feed. Precipitation of insoluble salts in the brine can limit the water recovery.

Since the first electrodialysis plants were produced in the early 1950s, several thousand brackish water

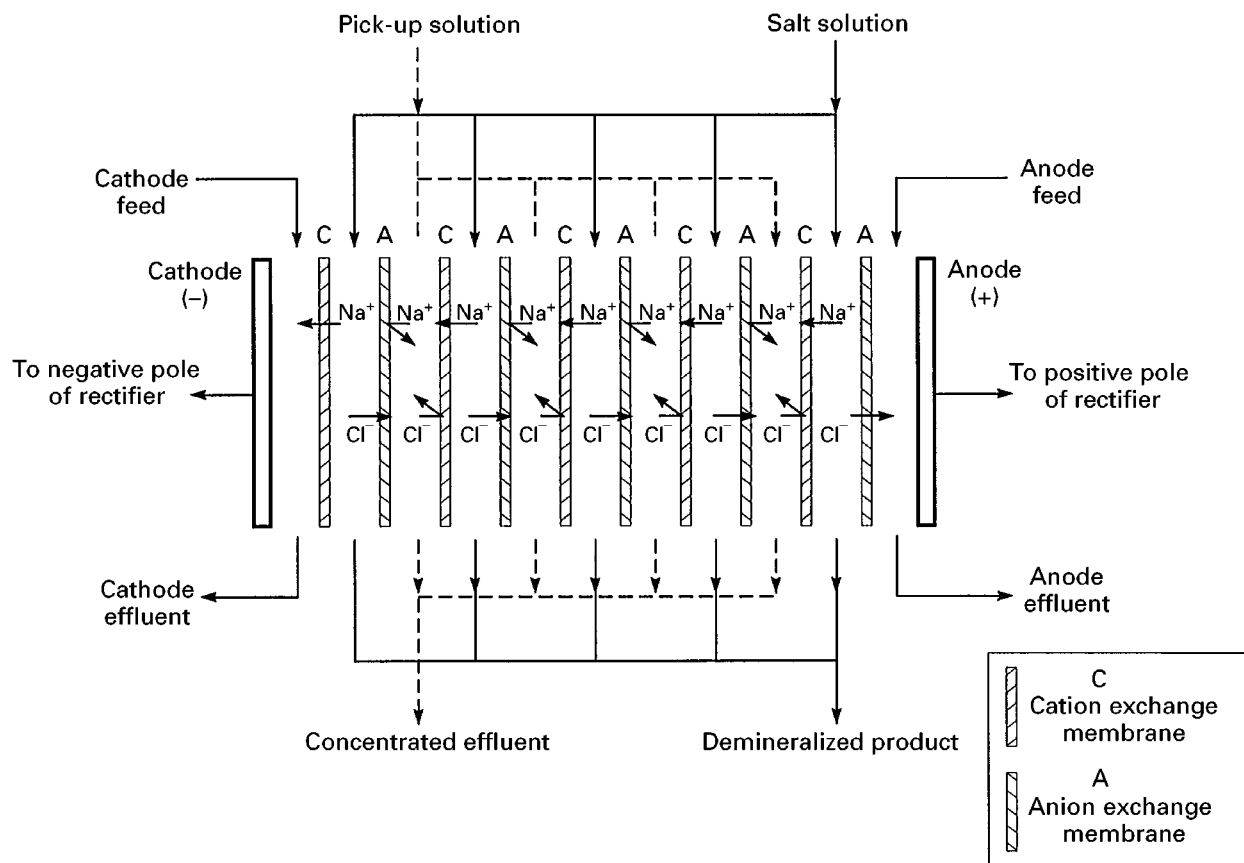

Figure 15 Schematic diagram of a plate-and-frame electrodialysis stack. Alternating cation- and anion-permeable membranes are arranged in a stack of up to 100 cell pairs.

electrodialysis plants have been installed around the world. Modern electrodialysis units are generally fully automated and require only periodic operator attention. This has encouraged installation of many small trailer-mounted plants. However, a number of very large plants with production rates of 10 million gal per day or more have also been produced.

The power consumption of an electrodialysis plant is directly proportional to the salt concentration in the feed water, and varies from 4 kWh per 1000 gal (4 MJ m^{-3}) for 1000 ppm feed water to 10–15 kWh per 1000 gal ($10\text{--}15 \text{ MJ m}^{-3}$) for 5000 ppm feed water. About one-quarter to one-third of this power is used to drive the feed water recirculation pumps.

Seawater A second major application of electrodialysis is the production of table salt by concentration of seawater. This process is only practised in Japan, which has no other domestic salt supply. The process is heavily subsidized by the government. Total production is approximately 1.2 million tons per year of salt, with more than 500 000 m² of membrane used in the plants.

A flow scheme for one such seawater salt-production plant is shown in Figure 16. A cogeneration power plant produces the power required for the electrodialysis operation, which concentrates the salt in seawater to about 18–20 wt%. Waste steam from

the power plant is then used to concentrate the salt further by evaporation.

Gas Separation

The process The study of gas permeation through membranes has a long history dating back to the work of Thomas Graham in the mid-nineteenth century. However, the first systematic studies with polymers of the type used today did not begin until 100 years later.

The mechanism of gas permeation developed in the 1950s and 1960s was the solution-diffusion model. In this model, the rate of diffusion through the polymer membrane is governed by Fick's law of diffusion. For simple gases, it can be shown that Fick's law leads to the expression

$$J = \frac{Dk\Delta p}{l} \quad [4]$$

where J is the membrane flux ($\text{cm}^3(\text{STP})/\text{cm}^2 \text{ s}$), k is the Henry's law sorption coefficient linking the concentration of gas in the membrane material to the pressure of the adjacent gas ($\text{cm}^3(\text{STP})/\text{cm Hg}$), Δp is the partial difference across the membrane, l is the membrane thickness (cm), and D is the permeant diffusion coefficient ($\text{cm}^2 \text{ s}^{-1}$), a measure of the permeant's mobility in the membrane. This expression can be further simplified to

$$J = \frac{P\Delta p}{l} \quad [5]$$

where P is a permeability, equal to the product Dk , and is a measure of the rate at which a particular gas moves through the membrane of a standard thickness (1 cm) under a standard driving pressure (1 cm Hg). The permeability unit, $1 \times 10^{-10} \text{ cm}^3 (\text{STP}) \text{ cm}/\text{cm}^2 \text{ s cm Hg}$, is called a Barrer, after R.M. Barrer, a pioneer in membrane permeation studies.

A measure of the ability of a membrane to separate two gases (1) and (2) is the ratio of their permeabilities, called the membrane selectivity, α :

$$\alpha_{1,2} = \frac{P_1}{P_2} = \frac{D_1}{D_2} \times \frac{k_1}{k_2} \quad [6]$$

The factors that determine membrane permeability can best be understood by considering the component terms D and k . For simple gases, the diffusion coefficient tends to decrease with increasing permeant diameter, because large molecules interact with more segments of the polymer chains and are thus less mobile. On the other hand, the sorption

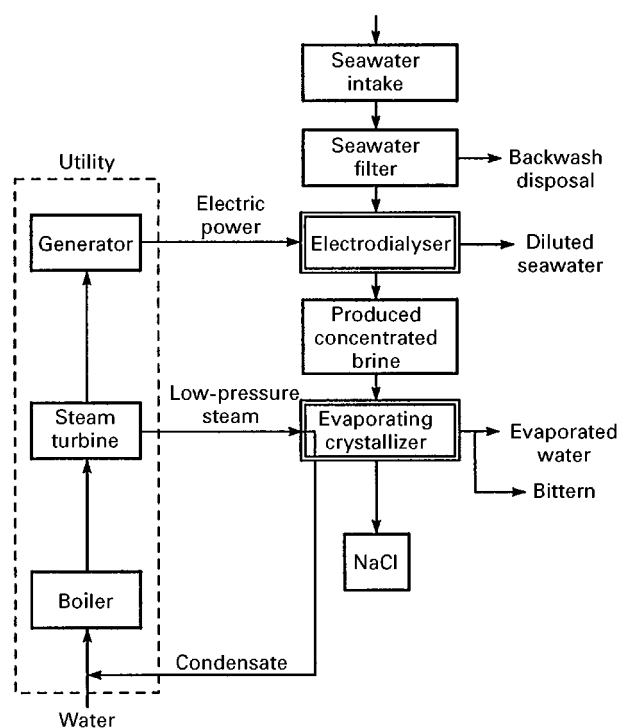

Figure 16 Flow scheme of a typical electrodialysis process used in a seawater salt concentration plant.

coefficient of gases increases with the condensability of the gas. Normally, the sorption coefficient also correlates with molecular diameter, larger molecules being more condensable than smaller molecules, and the Henry's law sorption coefficient increases with increasing permeant diameter. Thus, the effect of increasing permeant size on permeability is a balance between the opposing effects of diffusion coefficient, which decreases with increasing size, and solubility, which increases with increasing size. This balance determines the selectivity of a membrane for any pair of gases and is a function of the membrane material.

In glassy, rigid polymers such as polysulfone or polyimides, permeant diffusion coefficients are most important. Therefore, these polymers preferentially permeate the small, noncondensable gases, hydrogen, nitrogen and methane, over the larger, condensable gases, propane and butane. On the other hand, in rubbery polymer such as silicone rubber (polydimethylsiloxane), permeant solubility coefficients are most important. Therefore, these polymers preferentially permeate the larger, more condensable gases, propane and butane, over the smaller, noncondensable gases, hydrogen, nitrogen and methane.

Applications The principal developed gas separation processes are listed in Table 2. The first large-scale commercial application of gas separation was the separation of hydrogen from nitrogen in ammonia purge gas streams. The process, launched in 1980 by Permea, then a Division of Monsanto, was followed by a number of similar applications, such as hydrogen/methane separation in refinery off-gases and hydrogen/carbon monoxide adjustment in oxo-chemical synthetic plants.

Following Permea's success, several US companies produced membrane systems to treat natural gas streams, particularly to remove carbon dioxide. The goal is to produce a stream containing less than 2% carbon dioxide to meet the national pipeline specifications and a permeate enriched in carbon dioxide

Figure 17 Flow scheme of (A) a one-stage and (B) a two-stage membrane gas separation system for the separation of carbon dioxide from natural gas.

to be flared or reinjected into the ground. Currently, cellulose acetate is the most widely used membrane material for this separation, but because the carbon dioxide/methane selectivity of cellulose acetate is only 15–20, two-stage systems are often required to achieve a sufficient separation. More selective polyimide membranes are beginning to replace cellulose acetate membranes in this application. Flow schemes for a one-stage (A) and a two-stage (B) cellulose acetate membrane system for carbon dioxide/natural gas separations are shown in Figure 17. The single-stage system has a low capital cost, but 12.7% of the methane in the gas is lost with the carbon dioxide. This loss becomes unacceptable for large systems, so a two-stage unit is used. The methane loss is reduced to less than 2% but at the expense of more membrane area and a large compressor. The membrane process is generally best suited to relatively small streams in the 5–20 MMscfd range, but the economics of the process have slowly improved over

Table 2 Membrane gas separation applications

Separation	Status
H ₂ /N ₂ , CO, CH ₄ , etc.	~500 units installed. Various hydrogen recovery applications in refineries, petrochemical and ammonia plants
CO ₂ /CH ₄	~200 units installed, some very large (5000–50 000 scfm) to separate carbon dioxide from natural gas
N ₂ /air	~5000 units installed, most small in the 50–500 scfm range (98–99.5% nitrogen)
Organic solvent vapour/air, N ₂	~100 units installed. Diverse applications include gasoline vapour recovery at oil terminals, recovery of monomers from reactor vents
H ₂ O/air	Many thousands of small modules sold for drying compressed air

the years and more than 200 natural gas treatment plants have now been installed – some quite large.

By far the largest gas separation process in current use is the production of nitrogen from air. The first membranes used for this process were based on polysulfone, poly(trimethylpentane) and ethyl cellulose. These polymer materials had oxygen/nitrogen selectivities of 4 to 5, and the economics of the process were marginal. The second-generation materials now used have selectivities in the range 6 to 7. With these membranes, the economics of nitrogen production from air are very favourable, especially for small plants producing 50–500 scfm of nitrogen; 5000 of these small systems are now in operation. In this range, membranes are the low-cost process, and most new nitrogen plants use membrane systems.

A growing application of membrane systems is the removal of condensable organic vapours from air and other streams. Unlike the process described above, organic vapour separation uses rubbery membranes, which are more permeable to the organic vapour. More than 100 organic vapour recovery plants have been installed. In Europe, most of the plants recover gasoline vapours from air vented during transfer operations; in the USA, most plants recover chlorinated and fluorinated hydrocarbons from refrigeration or chemical processing streams. Separation of propylene from nitrogen in polyolefin plants is an emerging application worldwide.

Pervaporation

The process Pervaporation is a membrane process used to separate liquid mixtures. The feed liquid contacts one side of a membrane, which selectively permeates one of the feed components, as shown in Figure 18. The permeate, enriched in this component, is removed as a vapour from the other side of the membrane. The driving force for the process is the low vapour pressure on the permeate side of the membrane, which is generated by cooling and condensing the permeate vapour. The separation achieved is proportional to the differences in rates of permeation of the components of the mixture through the membrane.

Pervaporation offers the possibility of separating solutions, mixtures of components with close boiling points, or azeotropes that are difficult to separate by distillation or other means. An illustration of the ability of pervaporation membranes to break azeotropes is shown in Figure 19 for the separation of benzene/cyclohexane mixtures. The vapour–liquid equilibrium for the mixture shows that benzene/cyclohexane mixtures form an azeotrope at approximately 50% benzene. Distillation is unable to

Figure 18 In the pervaporation process, a liquid contacts the membrane, which preferentially permeates one of the liquid components as a vapour. The vapour, enriched in the more permeable component, is cooled and condensed, spontaneously generating a vacuum that drives the process.

separate a feed stream of this composition. However, pervaporation treatment of this mixture produces a vapour permeate containing more than 95% benzene.

The first systematic work on pervaporation was done by Binning and co-workers at American Oil in the 1950s. The process was not commercialized at that time and remained a mild academic curiosity until 1982, when GFT (Gesellschaft für Trenntechnik

Figure 19 Fraction of benzene in permeate as a function of feed mixture composition for pervaporation at the reflux temperature of a binary benzene/cyclohexane mixture. (Reprinted with permission from *Industrial and Engineering Chemical Research* 22 (1983) 313. Copyright 1983 American Chemical Society.)

GmbH, Germany) installed the first commercial pervaporation plant. That plant separated water from concentrated alcohol solutions; GFT has since installed more than 50 such plants. The ethanol feed to the membrane generally contains $\sim 10\%$ water. The pervaporation process removes the water as the permeate, producing pure ethanol with less than 1% water, and avoiding all the problems of azeotropic distillation.

Spurred on by this success, a great deal of effort is being made to apply pervaporation to other difficult separations. Exxon, for example, pursued the separation of hydrocarbon mixtures containing aromatics and aliphatics, a major separation problem in refineries. Another application is the separation of dissolved volatile organic compounds (VOCs) from water, developed by Membrane Technology and Research, Inc.

Applications To date, the largest application of pervaporation is the dehydration of ethanol or isopropanol. This process has been pioneered by GFT, now a division of Sulzar, using polyvinyl alcohol composite membranes that are far more permeable to water than alcohol. A flow scheme of a GFT plant combining distillation and pervaporation to produce dry alcohol is shown in Figure 20. The distillation column produces an ethanol overhead stream containing 85–90% ethanol which is fed to the pervaporation system. To maximize the vapour pressure driving force across the membrane the pervaporation module usually operates at a temperature of 105–130°C, corresponding to a feed stream vapour pressure of 2–6 atm. The permeate vapour is cooled and condensed at 0 to -10°C . The permeate contains 40–50% ethanol which is recycled to the distillation column; the residue stream is better than 99.5 wt% ethanol. Most of the installed solvent de-

hydration systems have been for ethanol dehydration, but applications to other solvents, including isopropanol, glycols, acetone and methylene chloride, have also been studied.

The only other commercial pervaporation application is the separation of dissolved VOCs from water. Relatively hydrophobic composite membranes, such as silicone rubber coated on a microporous polyimide support membrane, are used. Extremely high separation factors can be obtained for the more hydrophobic VOCs such as toluene, benzene, chlorinated solvents, esters and ethers. Frequently the VOC in the condensed permeate is enriched 100- to 1000-fold over the feed. Target applications include removal of VOCs from industrial wastewater streams and the recovery of volatile flavour and aroma components in the food processing industry. The GC traces in Figure 21 illustrate the concentration and recovery of orange juice flavours from the water evaporated from orange juice obtained by pervaporation.

The current commercial pervaporation processes involve the separation of organics and water. This separation is relatively easy, because organic solvents and water have very different polarity and exhibit distinct membrane permeation properties. No commercial pervaporation systems have yet been developed for the separation of organic/organic mixtures. However, current technology now makes development of pervaporation for these applications possible, and the process is being actively developed by a number of companies. The first pilot-plant results for an organic–organic application – the separation of methanol from methyl *t*-butyl ether/isobutene mixtures – was reported by Separex in 1988. This is a particularly favourable application, and available cellulose acetate membranes achieve a good separation. More recently, Exxon started a pervaporation pilot plant for the separation of

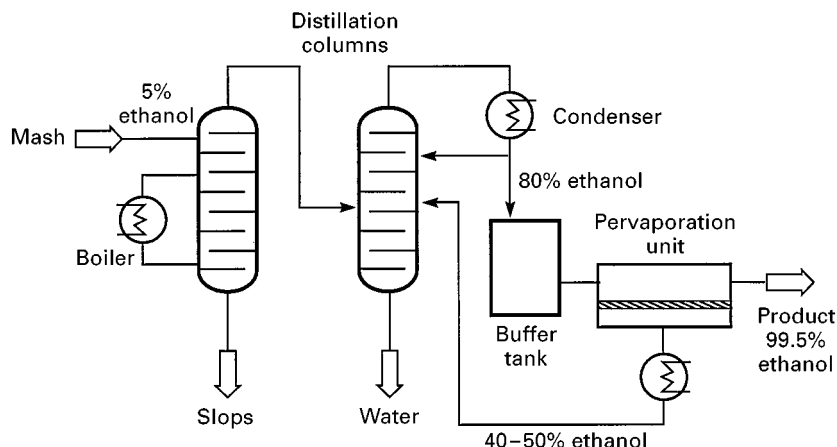

Figure 20 Flow scheme of an integrated distillation/pervaporation plant for ethanol recovery from fermentors.

Figure 21 HPLC traces showing recovery of flavour and aroma components from orange juice evaporation condensate by pervaporation.

aromatic/aliphatic mixtures, using polyimide/polyurethane block copolymer membranes.

Dialysis

The process Dialysis was the first membrane process to be used on an industrial scale with the development of the Cerini dialyser in Italy. The production of rayon from cellulose expanded rapidly in the 1930s, and a need arose to recover sodium hydroxide from hemicellulose/sodium hydroxide solution by-product streams formed in the process. A finely microporous membrane was used to separate the concentrated hemicellulose solution from water. The smaller sodium hydroxide molecules diffuse across the membrane down a concentration gradient to produce an uncontaminated product stream, as shown in **Figure 22**.

With the development of ultrafiltration and microfiltration membranes in the 1960s and 1970s, industrial applications of dialysis largely disappeared because dialysis membranes were slow and unselective compared to the newer technologies. However, in the medical area, two very large applications have been

Figure 22 The separation of sodium hydroxide from hemicellulose by dialysis. This separation became important in the production of rayon in the 1930s and 1940s.

developed, namely the dialysis of blood – haemodialysis – in the artificial kidney, and the related process used to exchange oxygen and carbon dioxide in blood in the artificial lung. Both processes use the low-pressure, mild conditions of dialysis.

Applications

Haemodialysis (artificial kidney) The kidney is a key component in the body's waste disposal and acid-base regulation mechanism. Approximately 1 in every 10 000 persons will suffer irreversible kidney failure, which before 1960 was invariably fatal. Now a number of treatments, of which haemodialysis is by far the most important, can maintain these patients. As many as 800 000 patients worldwide are treated by haemodialysis devices. Each patient is dialysed two to three times per week with a dialyser that contains about one square metre of membrane area. Economies of scale allow the membrane modules to be produced at about US\$15 each. The devices are generally disposed of after one or two uses. As a result the market is about US\$1.3 × 10⁹ per year, making this the largest membrane separation process in terms of sales per year and membrane area used.

The first successful artificial kidney was constructed by Kolf and Berk in Holland in 1945. Over the next 20 years Kolf and others developed a number of improved devices, and by the 1960s the process began to be widely used. Early dialysers used coiled tubes or plate-and-frame designs. The development of hollow-fibre dialysers reduced costs considerably, making widespread use of the process possible. Each fibre dialyser contains 0.5–2.0 m² of membrane formed as fibres 0.1–0.2 mm in diameter. A typical dialyser module (**Figure 23**) contains several thousand fibres in a 2 in (5 cm) diameter tube 1–2 ft (30–60 cm) long. Blood flows down the bore of the fibre, and an isotonic saline solution is circulated around the outside. Urea, creatinin and other metabolites in the blood diffuse through the membrane to the dialysate solution. The process must be carried out

Figure 23 Schematic of a hollow-fibre haemodialyser.

slowly to avoid shock to the patient; typically 2–4 h are required to eliminate all of the accumulated toxins.

Blood oxygenators (artificial lungs) Blood oxygenators are used during heart surgery. Until the early 1980s direct oxygenation of blood was used to maintain patients during surgery. Rotating discs or small countercurrent contacting towers delivered oxygen to the blood and removed carbon dioxide. This procedure required a large volume of blood to prime the units and damaged the blood during long surgeries. The introduction of hollow-fibre membrane contactors largely solved both of these problems and was one reason for the dramatic expansion of open-heart surgery in the 1980s. Currently, about one million procedures are performed annually world-wide. A successful heart-lung must normally deliver about 250 cm³(STP) per min of oxygen and remove about 200 cm³(STP) per min of carbon dioxide. Microporous polyolefin hollow-fibre membrane modules with a membrane area of 2–10 m² are generally used.

Other Membrane Separation Processes

The seven processes described above represent the majority of commercial membrane separation technologies. However, a number of processes are still in the laboratory or early commercial stage and may yet become important. These processes are described briefly below.

Carrier-Assisted Transport

Carrier-assisted transport usually employs liquid membranes containing a complexing or carrier agent. The carrier agent reacts with one permeating component on the feed side of the membrane and then diffuses across the membrane to release the permeant on the product side of the membrane. The carrier agent is then reformed and diffuses back to the feed side of the membrane. Thus, the carrier agent acts as a shuttle to transport selectively one component from the feed to the product side of the membrane.

Facilitated transport membranes can be used to separate gases; membrane transport is then driven by a difference in the gas partial pressure across the membrane. In the example shown in Figure 24, the carrier is haemoglobin, used to transport oxygen. On the upstream side of the membrane, haemoglobin reacts with oxygen to form oxyhaemoglobin, which then diffuses to the downstream membrane in-

Figure 24 Schematic examples of (A) facilitated and (B) coupled transport of gas and ions. The facilitated transport example shows the transport of oxygen across a membrane using haemoglobin as the carrier. The coupled transport example shows the transport of copper ions across the membrane using a liquid ion exchange reagent as the carrier.

terface. There, the reaction is reversed – oxygen is liberated to the permeate gas and haemoglobin is reformed. The haemoglobin then diffuses back to the feed side of the membrane to pick up more oxygen. In this process haemoglobin acts as the shuttle, transporting oxygen selectively through the membrane. Other gases, such as nitrogen, which do not react with the carrier, are left behind.

Coupled transport is similar to facilitated transport and also incorporates a carrier agent in the membrane. However, in coupled transport the carrier agent couples the flow of two species. Because of this coupling, one of the species can be moved against its concentration gradient, provided the concentration gradient of the second coupled species is sufficiently large. In the example shown in Figure 24, the carrier is an oxime that forms an organic-soluble complex with copper ions. The reaction is reversed by hydrogen ions. On the feed side of the membrane, two oxime carrier molecules pick up a copper ion, liberating two hydrogen ions to the feed solution. The copper–oxime complex then diffuses to the downstream membrane interface, where the reaction is reversed because of the higher concentration of hydrogen ions in the permeate solution. The copper ion is liberated to the permeate solution and two

hydrogen ions are picked up. The reformed oxime molecules diffuse back to the feed side of the membrane. Metal ions can also be selectively transported across a membrane, driven by a flow of hydrogen or hydroxyl ions in the other direction.

Because the facilitated and active transport processes employ a reactive carrier species, very high membrane selectivities can be achieved – often far larger than those achieved by other membrane processes. This has maintained interest in facilitated transport since the 1980s, yet no significant commercial applications exist or are likely to exist in the immediate future. The principal limitations are the physical instability of the liquid membrane and the chemical instability of the carrier agent.

Membrane Reactors

In membrane reactors, the membrane is used to shift a chemical equilibrium or separate the products of a reaction. A wide variety of processes have been suggested, and a few have reached the commercial stage. A simple example is shown in Figure 25 – the reaction of *n*-butane to butadiene and hydrogen:

$$\text{C}_4\text{H}_{10} \rightleftharpoons \text{C}_4\text{H}_6 + 2\text{H}_2$$

This is an equilibrium reaction and in a conventional process a mixture of components is withdrawn from the reactor, separated, and the unreacted *n*-butane recirculated to the feed. In the membrane reactor, hydrogen is removed through the membrane so that the chemical equilibrium in the reactor is shifted to the right and the conversion of *n*-butane to butadiene is increased. Essentially pure butadiene leaves the reactor. This type of process is the subject of a considerable research effort, mostly using ceramic membranes operating at high temperatures. The development of these devices for the production of syngas (a mixture of carbon monoxide and hydrogen) is the focus of very large research programmes at Air Products and Standard Oil. Promising results have been obtained in the laboratory, but scale-up to an economical process is still far off.

Membrane Contactors

In the membrane separation processes discussed so far, the membrane acts as a selective barrier allowing

Figure 25 Schematic of a membrane reactor to separate butadiene from *n*-butane.

Figure 26 Schematic showing application of a membrane contactor to remove dissolved oxygen from water. This process is used to prepare power plant boiler feed water.

relatively free passage of one component while retaining another. In membrane contactors the membrane function is to provide an interface between two phases but not to control the rate of passage of permeants across the membrane. An example of this technology, in which the membrane is used in a process to deoxygenate water, is shown in Figure 26.

A hollow-fibre microporous membrane separates the oxygen-containing water from the nitrogen sweep gas. Even though the dissolved oxygen concentration in the water is very low, its equilibrium concentration in the gas phase in contact with the water is several thousand times higher. This means that oxygen permeation through the membrane down the concentration gradient to the nitrogen sweep gas is high. The membrane provides a large surface contact area between the water and nitrogen sweep gas but does not affect the relative permeabilities of oxygen and water vapour through the membrane. In this type of application, the membrane serves as a contactor or phase separator. Exactly the same separation could be achieved by running the water and nitrogen countercurrent to each other in a packed tower, but membrane contactors are much more compact. Membrane contactors are typically shell- and tube-devices containing microporous capillary hollow-fibre membranes. The membrane pores are made sufficiently small that capillary forces prevent direct mixing of the two phases on either side of the membrane.

A small market has already developed for membrane contactors to degas ultrapure water for the electronics industry and boiler feed water for power

plants. The long-term goal of the process is to replace packed towers in conventional absorber–stripper operations. Practical problems related to membrane fouling and lifetime are the principal limitations.

The Future

Since the 1970s there has been a period of very rapid growth for the membrane separation industry. Total sales for all membrane applications have grown approximately 400-fold to the US\$3–4 × 10⁹ per year level. In the areas of microfiltration, ultrafiltration, reverse osmosis, electrodialysis and dialysis, the technology is relatively mature. Significant growth is still occurring, however, as membranes continue to displace more conventional separation techniques. The most rapidly expanding area is gas separation, which has grown to a US\$150 × 10⁶ per year business in just a few years. Gas separation is poised to grow a further two- or three-fold as the technology is used more widely in the refinery, petrochemical and natural gas processing areas. If the development of ceramic oxygen-permeable membranes for syngas membrane reactors is successful, a membrane process that could change the basis of the chemical industry would then be available.

Historical Development

In 1556, an extraordinary book entitled *De Re Metallica, Libri XII* appeared in Basel. The author was a German physician, naturalist and mineralogist, calling himself Georgius Agricola (originally called Georg Bauer), living in Jáchymov, Bohemia, from 1494 to 1555. Agricola described, in a fascinating manner, the contemporary advances in metals and

minerals recovery and gave us a very detailed report on the sophisticated technologies of his epoch. This late medieval period saw a true expansion of science and technology in Europe. Winston Churchill once said: ‘... from this date, 1492, a new era in the history of mankind takes its beginning’. As many metal recovery processes used at that time were based on various separations of particulate matter and *De Re Metallica, Libri XII* seems to be the first printed review of separation technologies, it is fitting to acknowledge Agricola’s publication priority in this field and to consider his book as the beginning of a modern scientific approach to particle size separations.

The reproduction of a rendering in **Figure 1** taken from Agricola’s book shows a surprisingly sophisticated device for gold (and other metals) recovery by ‘panning’ or ‘sluicing’ which used gravity and

¹This article does not deal with the important particle separation techniques of filtration, flotation and the use of membranes which are dealt with elsewhere in the Encyclopedia.

Figure 1 Mediaeval device for the recovery of gold particles and minerals from sand, clay, and soil blends by combining the sedimentation and quasi-horizontal stream of water, accompanied by vigorous manual stirring of the mud cake. (Bottom) The author of the book *De Re Metallica, Libri XII*, Georgius Agricola.

a stream of running water to separate gold particles from other solid material (soil, clay, sand, etc.). Astonishingly, this technology dates back to at least 4000 to 5000 BC.

Original scientific discoveries, outstanding inventions and innovations in technology representing the

important achievements at a given moment reflect continuity of imagination throughout the long history of civilization. When looking for the background and genesis of modern and powerful separation methodologies and technologies, very often natural analogies can be found at a macroscopic level. An image of a river meandering through the countryside and removing soil, clay, sand, and stones from a river bank, carrying them off in the stream, and depositing them later at other places, is one such example. On the other hand, although ancient technologies can have essentially the same goal (separation), in a manner similar to that in which 'cat's cradle' is equivalent to a sophisticated electronic computer game, the intellectual progress is evident.

Dry and wet sieving, sedimentation, and filtration are probably the most ancient, intelligently applied, separation processes on which the foundations of modern separation science stand. These processes were originally exploited for the separations of disintegrated matter whose average 'particle' size was somewhere between millimetre and centimetre fractions, sometimes even bigger. Slowly, the need to separate smaller and smaller particle size material became apparent. The old-fashioned but transformed methods still afforded positive answers to questions which appeared in relation to the new separation problems. However, these transformations gave rise to newer methods which, together with the discovery and invention of completely new principles, symbolize the state of the art of particle separation.

Particles, Sizes, and Methods

In order to make clear what this article deals with, the useful and necessary terms, limits and conditions must be defined. *Particles*, within the frames of this text, is an ensemble of single subjects of disintegrated matter which is dispersed in a continuum fluid or *in vacuo*. One particle, regardless of its size, is usually not identical with one molecule but with a large number of molecules aggregated by physical forces. In the case of polymeric matter, however, one macromolecule can be identified with one particle, under certain conditions. The second important attribute which defines one particle is that, physically, it represents a subject delimited in three-dimensional space by a phase discontinuity. The particles, representing one discontinuous phase which can be solid or liquid, are dispersed in a second continuous phase which is gaseous or liquid.

As concerns the *sizes* of the particles, a strict definition is less easy, because the effective dimension(s) (independently of the physical shape of each individual particle) can vary as a function of the

chemical character of the surrounding dispersing fluid but also of the imposed physical conditions: obvious ones, such as, e.g., the temperature, and less obvious as, e.g., the electric charge, etc. Moreover, it has to be taken into account that the results of the measurements of the particle size can strongly depend on the method of its determination. As a result, the questions are not only what the size that we obtain from a particular measuring method means and whether the result corresponds to a true size, but also what kind of effective size we measure by applying any particular method. Not only one but many effective sizes obtained by different measuring methods can correspond to the physical reality (they all can be 'true'). This is due to the fact that the measured data can contain various information on the particle-dispersing fluid and particle-particle interactions, on the size fluctuations in time, on the transport behaviour of the particles in the dispersing fluid, etc. Although all these phenomena can complicate the determination of a definite particle size, they provide much useful information on the whole dispersed particulate system. Having in mind these complications, we can define the range of particle sizes of practical interest as lying within the range from a diameter of few nanometres to thousands of micrometres.

The definition and limitation of the particles and the particle size ranges, as outlined, determine the relevant separation *methods*. Those methods can be considered relevant that are directly related to the separation according to differences in particle size or concerned indirectly due to the fact that they can provide complementary information necessary to an accurate interpretation of the experimental data obtained from particle size-based separations.

Objectives and Methods

The aim of any separation, including particle size separation, is either analytical or preparative. *Analytical separations* are generally used to increase the sensitivity or selectivity of the subsequent analytical measurement, or to obtain more specific information about the analysed sample. Very often, the original sample is a complicated mixture making the analysis possible only with a prior separation step. Hence, the original multicomponent sample to be analysed must first be separated into more or less pure fractions. Whenever the samples are of particulate character and/or of biochemical or biological origin, direct analysis without preliminary separation is often impossible. An accurate analytical result can be obtained from any analytical separation method by employing an appropriate treatment and interpretation of the experimental data. Separation is usually based on the differences in extensive properties, such as

the mass or size of the particles, or according to intensive properties, such as density, electrophoretic mobility, etc. If the relationship between the separation parameters and the size of the separated particles is known or can be predetermined by using an appropriate calibration procedure, the characteristics of an unknown analysed sample can be evaluated quantitatively. The particle size distributions of the analysed samples are determined conveniently from the record of a coupled detector: a fractogram. Detailed information concerning the associated properties of the separated and characterized particles and/or composition of the analysed system which can be extracted from the fractogram represents more sophisticated application of a particular separation method.

Preparative separations are aimed at obtaining a significant quantity of the separated fractions from the original sample. The fractions are subsequently used for research or technological purposes, for detailed analysis of various effective sizes, for the determination of the structure or chemical composition of the particles of a given size, etc. The practical preparative separations can range from laboratory microscale, which cannot be experimentally distinguished from analytical separations, up to industrial macroseparation units.

Analytical and preparative separations are fundamentally identical so that, consequently, we do not distinguish between them and all separation methods are described and discussed from the point of view of the principles involved by making comments on their specific applications only if the discussed technique exhibits particular characteristics predetermining it for a special analytical or preparative purpose.

The most suitable and widespread methodologies for particle size separations described below, starting from the most versatile to more specific ones, are:

- field-flow fractionation
- size-exclusion chromatography
- hydrodynamic chromatography
- centrifugation
- electrophoresis

Besides these modern techniques, some classical procedures mentioned above such as wet or dry sieving, filtration, etc., should not be forgotten.

Field-Flow Fractionation

Field-flow fractionation (FFF) is a relatively new but important and versatile method suitable for the separation and characterization of particles in the submicron and micron ranges. It has been developed over the last three decades into a complex of specific methods and techniques.

Principle of Separation

Separation in FFF is based on the action of effective physical or chemical forces across the separation channel in which the particles are transported due to the flow of a carrier liquid. The field interacts with the particles, separating and concentrating them at the appropriate positions inside the channel. The concentration gradient so formed induces an opposition diffusion flux. When equilibrium is reached, a stable concentration distribution of the particles across the channel is established. Simultaneously, a flow velocity profile is formed across the channel in the longitudinal flow of the carrier liquid. As a result, the particles are transported longitudinally at different velocities depending on the transverse positions of their zones and are thus separated. This principle is shown in Figure 2. The carrier liquid is pumped through the sample injector to the fractionation channel. The detector connected at the end allows the recording of the fractogram.

Separation Mechanisms

Two particular mechanisms, *polarization* and *focusing*, can govern the separation. The components of the fractionated sample can be differently compressed to the accumulation wall of the channel or focused at different levels. Polarization and focusing FFF have many common characteristics such as the experimental procedures, instrumentation, data treatment, and the range of potential applications. The separation is carried out in one liquid phase. The absence of a stationary phase of large surface area can be of fundamental importance for the fractionation of biological particles whose stability against degradation can be sensitive to interactions with the surfaces. The strength of the field can be easily controlled to manipulate the retention. Many operational variables can be programmed.

The *polarization* FFF methods are classified with regard to the character of the applied field, while the

focusing FFF methods are classified according to the combination of various fields and gradients. Although some earlier separation methods are also based on the coupled action of field forces and hydrodynamic flow, the beginning of FFF proper can be attributed to Giddings who in 1966 described the general concept of polarization FFF. Focusing FFF was originally described in 1982.

Polarization FFF methods make use of the formation of an exponential concentration distribution of each sample component across the channel with the maximum concentration at the accumulation wall which is a consequence of constant and position-independent velocity of transversal migration of the affected species due to the field forces. This concentration distribution is combined with the velocity profile formed in the flowing liquid.

Focusing FFF methods make use of transversal migration of each sample component under the effect of driving forces that vary across the channel. The particles are focused at the levels where the intensity of the effective forces is zero and are transported longitudinally according to their positions within the established flow velocity profile. The concentration distribution within a zone of a focused sample component can be described by a nearly Gaussian distribution function.

Retention

The retention ratio R is defined as the average velocity of a retained sample component divided by the average velocity of the carrier liquid which is equal to the average velocity of an unretained sample component:

$$R = \frac{v_{r,ave}}{\langle v(x) \rangle}$$

FFF is usually carried out in channels of simple geometry allowing calculation of the rigorous relationship between the retention ratio and the size of the separated particles. If this relationship is difficult to determine, a calibration can be applied. The particle size distribution (PSD) in both cases is determined from the fractogram.

Zone Dispersion

The separation process is accompanied by the zone spreading which has a tendency to disperse the concentration distribution already achieved by the separation. The conventional parameter describing the efficiency of the separation is the height equivalent to a theoretical plate H :

$$H = L \left(\frac{\sigma}{V_R} \right)^2$$

Figure 2 Schematic representation of the general principle and experimental arrangement of field-flow fractionation: (1) pump; (2) injector; (3) separation channel; (4) external field; (5) hydrodynamic flow; (6) detector.

where V_R is the retention volume and σ is the standard deviation of the elution curve. The width of the elution curve reflects several contributions: longitudinal diffusion, nonequilibrium and relaxation processes, and spreading due to the external parts of the whole separation system such as injector, detector, connecting capillaries, etc. The sum of all contributions results in a curve shown in Figure 3 which exhibits a minimum. As the diffusion coefficients of the particles are very low, the longitudinal diffusion is practically negligible and the optimal efficiency (the minimum on the resulting curve) is situated at very low flow velocity. The instrumental and relaxation spreading can be minimized by optimizing the experimental conditions.

Applications of Polarization FFF

The character of the applied field determines the particular methods of polarization FFF. The most important of them are:

- sedimentation FFF
- flow FFF
- electric FFF
- thermal FFF

Sedimentation FFF is based on the action of gravitational or centrifugal forces on the suspended particles. The sedimentation velocity is proportional to the product of the effective volume and density difference between the suspended particles and the carrier liquid. The channel is placed inside a centrifuge rotor, as shown in Figure 4. The technique can be used for the separation, analysis and characteriza-

Figure 3 Dependence of the efficiency of FFF, expressed as the height equivalent to a theoretical plate H , on the average linear velocity of the carrier liquid $\langle v(x) \rangle$.

tion of polymer latex particles, inorganic particles, emulsions, etc. The fractionation of colloidal particles in river water, diesel exhaust soot, and of the nuclear energy-related materials, are typical examples of the use of sedimentation FFF in the investigation of environmental samples. Droplets of liquid emulsions can also be separated and analysed. Biopolymers and particles of biological origin (cells) belong to the most interesting group of objects to be separated by sedimentation FFF. The performance of sedimentation FFF is superior to, or as good as, those of other separation methods. A complication in interpreting the experimental data is due to the fact that the retention is proportional to the product of particle size and density. When performing the fractionation in one carrier liquid only, the density must be assumed constant for all particles. However, it is possible to determine the size and density of the particles independently if the fractionations are performed in carrier liquids of various densities.

An example of a typical application of sedimentation FFF shown in Figure 5 allowed detection of a bimodal PSD in a sample of a polymer latex. The order of the elution from the small to the large diameter particles corresponds to the polarization mechanism. Figure 6 shows a rapid, high resolution sedimentation FFF of the polymer latex particles. In this case, the mechanism of steric FFF dominates, and the order of the elution is inverted.

Flow FFF is a universal method because different size particles exhibit differences in diffusion coefficients which determine the separation. The cross-flow, perpendicular to the flow of the carrier liquid along the channel, creates an external hydrodynamic field which acts on all particles uniformly. The channel, schematically demonstrated in Figure 7, is formed between two parallel semipermeable

Figure 5 Fractogram of poly(glycidyl methacrylate) latex showing a bimodal character of the PSD.

membranes fixed on porous supports. The carrier liquid can permeate through the membranes but the separated particles cannot. Separations of various kinds of particles such as proteins, biological cells, colloidal silica, polymer latexes, etc., have been described.

Electric FFF uses an electric potential drop across the channel to generate the flux of the charged particles. The walls of the channel are formed by semipermeable membranes as in flow FFF. The particles exhibiting only small difference in electrophoretic mobilities but PSD and, consequently, important differences in diffusion coefficients, can be determined. The advantage of electric FFF compared with electrophoretic separations, e.g., with capillary electrophoresis, is that high electric field strength can be achieved at low absolute values

Figure 6 Fractogram of high-speed high resolution sedimentation FFF of latex beads.

of the electric potential due to the small distance between the walls of the channel. Electric FFF is especially suited to the separation of biological cells as well as to charged polymer latexes and other colloidal particles. The fractionation of the charged particles represents a vast application field for exploration.

Thermal FFF was the first experimentally implemented technique, introduced several years ago. Until now, it has been used mostly for the fractionation of macromolecules. Only very recently have attempts been made to apply this method to the fractionation of particles. The potential of thermal FFF justifies a description here, regardless of its recent limited use in particle separations. The temperature difference between two metallic bars, forming channel walls with highly polished surfaces and separated by a spacer in which the channel proper is cut, produces a flux in the sample components, known as the Soret effect, usually towards the cold wall. The particle sizes can be evaluated from an experimental fractogram by using an empirical calibration curve constructed with a series of samples of known sizes. This calibration can be used to determine the characteristics of an unknown sample of the same chemical composition and structure, with the same temperature gradient applied. The pressurized separation systems permit operation above the normal boiling point of the solvent used. The fractionations can be achieved in few minutes or seconds. The performance parameters favour thermal FFF over competitive methods.

Applications of Focusing FFF

Focusing FFF methods can be classified according to various combinations of the driving field forces

and gradients. The gradients proposed and exploited are:

- effective property gradient of the carrier liquid
- cross-flow velocity gradient
- lift forces
- shear stress
- gradient of the nonhomogeneous field action

Focusing can appear due to the *effective property gradient of the carrier liquid* in the direction across the channel combined with the primary or secondary transversal field. The density gradient in sedimentation–flotation focusing field-flow fractionation (SFFFF) or the pH gradient in isoelectric focusing field-flow fractionation (IEFFFF) has already been implemented for separation of polystyrene latex particles and of biological samples. Separation by SFFFF is carried out according to the density difference of the latex particles. An electric field can be applied to generate the density gradient in a suspension of charged silica particles. The separation by IEFFFF is carried out according to the isoelectric point differences by using the electric field to generate the pH gradient and to focus the sample components. A simple design of a channel for SFFFF is shown in Figure 8 and an example of the separation of two latex particles according to small density difference is demonstrated in Figure 9. The separation is very rapid and much less expensive when compared to isopycnic centrifugation.

The effective property gradient of the carrier liquid, e.g., the density gradient, can be preformed at the beginning of the channel and combined with the primary or secondary field forces. A step density gradient is formed in such cases but the preforming is not limited to a density gradient.

Figure 8 Schematic representation of the channel for focusing FFF in coupled electric and gravitational fields: (1) flow in; (2) flow out; (3) channel walls forming electrodes; (4) spacer.

Figure 9 Fractogram of two samples of polystyrene latex particles showing a good resolution obtained by focusing FFF while no detectable resolution was achieved under static conditions: (1) injection; (2) stop-flow period; peaks corresponding to particle diameters of 9.87 μm (3) and 40.1 μm (4).

The focusing appears in the *gradient of transverse flow velocity* of the carrier liquid which opposes the action of the field. The longitudinal flow of the liquid is imposed simultaneously. This elutriation focusing field-flow fractionation (EFFFF) method has been investigated experimentally by using a trapezoidal cross-section channel to fractionate micrometre-size polystyrene latex particles but the use of the rectangular cross-section channel is possible.

The *hydrodynamic lift forces* that appear at high flow rates of the carrier liquid combined with the primary field are able to concentrate the suspended particles into the focused layers. The retention of the particles under the simultaneous effect of the primary field and lift forces generated by the high longitudinal flow rate can vary with the nature of the various applied primary field forces.

The *high shear gradient in a carrier liquid* can lead to the deformation of the soft particles. The established entropy gradient generates the driving forces that displace the particles into a low shear zone. At a position where all the driving forces are balanced, the focusing of the sample components can appear. Although this method was originally proposed by applying a temperature gradient acting as a primary field and generating the thermal diffusion flux of the macromolecules which opposes the flux due to the

entropy changes generated motion, it should be applicable to soft particles as well.

A *nonhomogeneous high-gradient magnetic field* can be used to separate various paramagnetic and diamagnetic particles of biological origin by a mechanism of focusing FFF. A concentration of paramagnetic particles near the centre of a cylindrical capillary and the focusing of diamagnetic particles in a free volume of the capillary should occur. No experimental results have yet been published.

Other gradients and a variety of the fields can be combined to produce the focusing and to apply these phenomena for PSD analysis. This review of the mechanisms used in focusing FFF should give an idea of their potential.

Size-Exclusion Chromatography

Size-exclusion chromatography (SEC) is utilized for the fractionation and analytical characterization of macromolecules but also for the separation of particles. The term gel-permeation chromatography (GPC) is used simultaneously in the literature with almost equal frequency. Other terms employed to describe this separation method are steric-exclusion liquid chromatography, steric-exclusion chromatography, gel filtration, gel-filtration chromatography, gel chromatography, gel-exclusion chromatography, and molecular-sieve chromatography. Each reflects an effort to express the basic mechanism governing the separation but the appropriate choice is more a question of individual preference.

The historical origins of SEC date from the late 1950s and early 1960s. Using cross-linked dextran gels swollen in aqueous media, Porath and Flodin separated various proteins according to their sizes. The 'soft gel' column packing used in these experiments was applicable only at low pressure and, consequently, at low flow rates resulting in very long separation times. The first successful separation of a synthetic polymer by SEC was described by Vaughan who succeeded in separating low molar mass polystyrene in benzene on a weakly cross-linked polystyrene gel. Some years later, Moore described the separation of polymers on moderately cross-linked polystyrene gel column packings.

The first rigid macroporous packing, suited also for the separation of particles, was porous silica introduced in 1966 by De Vries and co-workers. This packing was fully compatible with both aqueous and organic solvents, exhibited a very good mechanical stability, but its use was restricted by strong nonsteric exclusion interactions between the silica surface and a number of separated species. In 1974, the appearance of the packings of small porous particles with

a typical diameter around 10 μm , instead of 50–100 μm particle diameter used in conventional SEC columns, resulted in an important technological improvement in SEC. The high pressure technology, the lowering of the column volume due to the use of small particle diameter packings and the high efficiency of the columns allowed the separation time to be reduced from hours to minutes. Other porous silica microparticle packings, introduced by Kirkland, Unger, and others, were resistant to the high pressure and compatible with the quasi-totality of the solvents. The undesired interactions were suppressed by organic grafting or by organic coating of the porous silica.

Principle of Separation

The separation mechanism can be explained on the basis of a specific distribution of the separated particles between the eluent outside the porous particles of the column packing (mobile phase) and the solvent filling the pores (stationary phase). This distribution is due to the steric exclusion of the separated particles from a part of the pores according to the ratio of their size to the size of the pores. The particles whose sizes are larger than the size of the largest pores cannot permeate the pores, passing only through the interstitial volume, i.e., through the void volume between the particles of the column packing, whereas very small particles may permeate all the pores. Particles of intermediate size are, to a greater or lesser extent, excluded from the pores. Hence, the elution proceeds from the largest particles to the smallest ones. This mechanism is schematically demonstrated in Figure 10.

The total volume of a packed chromatographic column, V_t , is given by the sum of the total volume of the pores, V_p , the volume of the matrix proper of the porous particles, V_m , and the interstitial or void volume, V_o , between the porous particles:

$$V_t = V_p + V_m + V_o$$

The retention volumes, V_R , of the separated particles lie within V_o and $V_o + V_p$. V_R of a uniform particle size fraction of the sample is defined as a volume of the eluent that passes through the column from the moment of the sample injection to the moment when the given particles leave the separation system at their maximal concentration. The retention can alternatively be expressed in time units as the retention time t_R . The particles permeating the pores are excluded from some of the pores and partially permeate the accessible pores. The retention volume of a given species can be written as:

$$V_R = V_o + K_{\text{sec}} V_p$$

Figure 10 Schematic representation of the chromatographic column for SEC. Column with the void volume between the spherical particles of the column packing, the structure of one porous particle with the pore and matrix volumes, and the imaginary shape of one pore allowing the total permeation of smallest separated particles, partial permeation of intermediate size particles, and exclusion of largest particles.

where K_{sec} is the formal analogue of the distribution coefficient between the mobile and stationary phases.

Separation Mechanisms

Many attempts have been made to explain the mechanism of separation in SEC but steric exclusion (or size exclusion) is accepted to be the main process governing the separation. This mechanism is based on a thermodynamic equilibrium between stationary and mobile phases. As the nature of the solvent is the same in both phases, the question is to explain the dependence of the distribution coefficient K_{sec} on the size of the separated species. One of the simplest approaches uses the above-mentioned geometrical models; nevertheless, the retention volume is determined not only by the accessibility of a part of the volume of the individual pores but also by the size distribution of the entire system of pores in the column packing material. The distribution coefficient for an individual pore depends on the ratio of the pore size to the size of the separated particles and can be expressed by:

$$K_{\text{sec}} = \frac{c_p}{c_o}$$

where the concentrations c_p and c_o refer to the pores and the interstitial volume. If the pore size distribution of the column packing particles is taken into consideration, the retention volume is given by:

$$V_R = V_o + \int_R^{r_{\text{max}}} K(R, r)_{\text{sec}} \phi(r) dr$$

where $\phi(r)dr$ is the total volume of the pores whose radii lie within r and $r + dr$, and R is an equivalent radius of the retained particles. Hence, the retention volume of a given particulate species is determined coincidentally by the accessibility of a part of the volume of the individual pores and by the size distribution of the entire system of pores inside the column packing particles. Although different column packings exhibit almost identical dependences of V_R on separated particles size, porosimetric measurements indicate various pore size distributions. This means that the relationship between the pore size distribution and the retention volume of the separated species is not so straightforward.

An interesting model of separation by flow was proposed by Di Marzio and Guttman. The porous

structure of the SEC column packing is approximated by a system of cylindrical capillaries. The separated species move down the pores by the action of the flow but cannot get nearer to the pore wall than a distance determined by their radius. Consequently, they move at a velocity higher than the average velocity of the liquid flow due to a parabolic flow-velocity profile established in an imaginary cylindrical pore. Hence, the retention is determined by the ratio of the pore to the particle diameter. There are several factors that militate against this separation mechanism. The model assumes that the liquid can flow through the pores, which will not be true in most cases with polymeric gel particles used as column packing materials. Moreover, even in those cases when the pores are open to through flow, their diameter in comparison with the size of the interstitial voids cannot allow the flow rate to be high enough to explain the real values of the retention volumes. For the same reason, the frequently used explanation of the SEC mechanism of separation by an oversimplified model of molecular sieving is not accurate. This model, however, explains quite well the separation of large particles in hydrodynamic chromatography where either very large open pores are present in the particles of column packing or the packing particles are not porous and the separation by flow is performed in the interstitial volume only.

More complicated mechanisms based on the interactions between the separated species and the stationary phase may occur in an SEC column in addition to the steric exclusion mechanism: adsorption, liquid-liquid partition, electrostatic repulsions between the separated particles and the packing material, etc. The pure SEC separation mechanism can be operating only if the column packing material and the solvent are chosen to suppress these secondary effects. If the distribution coefficient K_{sec} is larger than 1, it is certain that other interactions, e.g., adsorption, beside the steric exclusion mechanism come into play and increase the retention. Unfortunately, if K_{sec} lies between 0 and 1, it does not mean that secondary interactions are definitely not interfering. Although such interactions are secondary, they can either improve or worsen the resulting separation. From the thermodynamic point of view, the separation is carried out near equilibrium conditions and the distribution coefficient can be described by:

$$K_{\text{sec}} = \exp\left(\frac{-\Delta H^\circ}{RT}\right) \exp\left(\frac{\Delta S^\circ}{R}\right)$$

Dawkins and Hemming considered the enthalpic term on the right-hand side of this equation as a distribution coefficient, the value of which is unity,

provided that size exclusion is the only effective mechanism. In such a case, the entropic term represents the pure size-exclusion mechanism. If other attractive interactions come into play ΔH° becomes negative and, if some repulsive interactions are involved, ΔH° is positive.

Other mechanisms explaining the separation in SEC have been proposed but most of them apply exclusively to the separation of macromolecules. The details can be found in the specialized literature. The above-presented approaches give an accurate basic idea of the separation of particles by SEC.

Applications of SEC

SEC allows, with respect to the basic separation mechanism, separation of particles according to differences in their effective sizes. Its application to the separation of particles in the submicron size range is limited only by the availability of column packing materials having sufficiently large pore size diameters. In order to cover as large a range of sizes of commonly fractionated particles as possible, the column packing material should have the pore size distribution from a few tenths of nanometres to hundreds of nanometres. For technical reasons, it is only possible to prepare the packings with a limited range of pore sizes and the SEC separation system is composed of an assembly of several columns in series, packed with several particle packing materials of different porosities, or another possibility is to use only one column packed with a mixture of several different packing materials with various porosities. The selectivity and the resolution of such a separation system is, however, lower than a system with a more homogeneous distribution of the pore dimensions.

Besides standard particle size separations, SEC has been successfully applied to the analytical characterization of micelles and submicron particles. Under the appropriate experimental conditions it can be used for separations in organic solvents as well as in water, at elevated temperatures, etc. An interesting application of SEC is so-called *inverse SEC*. The difference, as compared to conventional SEC, lies in the column packing particles being analysed from the viewpoint of the pore size distribution or average pore size dimensions, using a series of well-characterized size standards.

The analytical application of SEC for the determination of PSD is related to the use of either any calibration procedure and/or to the coupling of the separation system with the detector, the response of which is proportional to the size-related property of the analysed particles such as, e.g., the intensity of the

scattered light. The coupling of the concentration-sensitive detector and a size-sensitive detector, together with the use of an appropriate calibration procedure for the separation system, allows extraction of more information on PSD and other structural parameters of the particles under study.

Hydrodynamic Chromatography

Hydrodynamic chromatography (HC), as a new method for the separation of the particles of submicrometre sizes, was described by Small in 1974. HC is not a variant of SEC although some processes can participate in the separation mechanisms of both methods. It is not a subtechnique of FFF although the hydrodynamic phenomena can actively participate in the separation mechanism of FFF whose fundamental characteristic is the selective migration of the separated species due to an effective field. Formally, HC could be considered as a limiting case of FFF when the intensity of an effective external field is zero.

Principle of Separation

The name of the method designates the principal mechanism governing the separation: hydrodynamic phenomena appearing in fluids flowing through porous media or in capillaries. The separation in HC is performed in a carrier liquid flowing either through the void volume of a packed column or inside an open capillary of small diameter. The separated particles are carried by the flow with a velocity higher than the average velocity of the carrier liquid due to the tendency of the particles to concentrate in a radial position where the streamline velocity is higher compared with the average velocity of the liquid. Such a radial position corresponds to an energy minimum of the particles migrating within the field of shear forces. The driving forces which cause the radial flux of the separated particles can be of very diverse character. Another phenomenon participating in the separation processes can be the steric exclusion of the particles from a part of the volume within which the carrier liquid can flow near the column packing surface or near the wall of an open capillary. The velocity of the carrier liquid decreases to zero toward these surfaces and only small separated particles which can approach the surface of the column packing or capillary wall can elute with slow velocity in the vicinity of these surfaces. This situation is demonstrated in **Figure 11** for a model case of the HC carried out in an open capillary.

Separation Mechanisms

According to Small, the separation in HC is governed by three contributing effects: hydrodynamic forces,

Figure 11 Schematic representation of the HC separation principle. Larger particles are excluded from the wall and can freely migrate only in a part of the volume of the capillary column. As a result, their elution times are shorter compared with the elution times of smaller particles.

electrostatic repulsions, and Van der Waals forces. The density of the separated particles influences only their mobility and rotational moments. Soft particles can be deformed due to the high shear stress and this effect can influence their retention volumes.

A model of the separation by flow was originally proposed by DiMarzio and Guttman to explain retention in SEC. Their model approximates the structure of a packed chromatographic column to a complex system of capillaries in which the separation is caused by the same steric exclusion phenomenon as shown in **Figure 11**. The average velocity of the carrier liquid in a cylindrical capillary is given by:

$$\langle v(r) \rangle = \frac{\Delta P R^2}{8\mu L}$$

where ΔP is the pressure drop along the capillary of the length L and the radius R , μ is the viscosity of the carrier liquid and r is the radial coordinate. The average velocity of uniform-sized particles is given by:

$$v_{\text{ave}} = \frac{\Delta P}{4\mu L} \left[R^2 - \frac{(R-a)^2}{2} - \gamma a \right]$$

where a is the radius of the separated particles. The last term of the equation represents the rotational moment of the particles which reduces the velocity of their axial migration. The resulting retention is defined, similarly as in FFF, by the ratio of both velocities:

$$R = \frac{v_{\text{ave}}}{\langle v(r) \rangle}$$

Whenever HC is carried out in an open capillary, the separation is clearly dominated by this mechanism. Many authors consider that particles do not move within all the sterically accessible volume but in an

annular volume which is determined by the radial forces generated by the flow of the carrier liquid. The particles carried by the flow undergo the effect of the radial force which concentrates them within the annular volume. This force is due to the combination of the rotational and translational movements of the particles and is analogous to the Magnuson effect.

The electrostatic double layer on the surface of the separated particles influences their effective sizes. The electrostatic double layer, on the surface of the chromatographic packing or of the wall of the capillary column, reduces the accessible volume of the column due to the repulsion of separated particles of the same charge. The increased concentration of ions (ionic force) in the carrier liquid causes the screening of the surface electric charges and, consequently, reduces all electrostatic interactions. On the other hand, the reduced repulsions allow the separated particles to approach within a small distance at which the attractive Van der Waals force become effective. As a result, the hydrodynamic phenomena and electrostatic repulsions dominate the separation mechanism at a low ionic force of the carrier liquid, while at a high ionic force, the separation is dominated by hydrodynamic forces and adsorption phenomena. The order of the elution can be inverted, the particles can form aggregates, and the separation can be completely perturbed by these effects.

Applications of HC

HC is widely used for the separations of particles of very different character, starting from inorganic particles, polymer latexes, and biological cells, to synthetic and natural molecules, oil emulsions, etc. Modern short capillary columns allow substantial reduction in the separation time and an increase in the efficiency and resolution. Although HC was originally developed for the separations of micrometre-sized particles, the size range of applications has recently been lowered to tens of nanometres. The example in **Figure 12** shows the chromatogram of three polymer latex size standards separated on an open capillary column. The separation was accomplished in one minute.

Centrifugation

Starting in the early 1920s with the famous work of Svedberg, centrifugation became probably the most popular method for separation of particles. Based on extensive knowledge and experience of the sedimentation of particles in a natural gravitational field, centrifugation, using more intense inertial forces gen-

Figure 12 Separation of different size polymer latexes by HC.

erated at slow rotational speeds, allowed the separations of relatively small particles. The invention of the ultracentrifuge (which uses extremely high speeds of rotation, allowing a reduction in the size limits of the separated species) and of new coupled detectors, upgraded a simple sedimentation fractionation technique into powerful separation methodology applicable to preparative separations as well as for analytical characterization of particles and macromolecules. The impressive progress in theory, methodology, techniques and applications was of a long-lasting nature, from the 1920s to the 1970s. Thereafter, some stagnation appeared but the beginning of the 1990 represented a renaissance era for analytical and preparative ultracentrifugation and derived techniques.

Principle of Separation

A particle suspended in a fluid settles under the effect of gravitational or inertial centrifugal force which is proportional to the effective mass of the particle, i.e., the difference between its true mass m and the mass of the same volume V of the suspending liquid, according to Archimedes principle:

$$F_1 = (mg - \rho Vg)$$

where g is the acceleration due to the gravitational or centrifugal field forces and ρ is the density of the suspending liquid. Force F_1 is opposed by the force of friction F_2 which is proportional to the velocity of sedimentation U with a constant of proportionality f , called the friction coefficient:

$$F_2 = fU$$

With the exception of the initial short period of time during which the sedimentation velocity of the particle increases until the steady state is reached at which both forces are equal, the velocity of sedimentation in a homogeneous liquid is constant. Stokes calculated the friction coefficient of hard spherical particles and obtained:

$$f = 6\pi\eta r$$

for a particle of the radius r sedimenting in a liquid of the viscosity η . Einstein derived the relationship between the friction and diffusion coefficients:

$$D = kT/f$$

It is evident that the sedimentation processes in homogeneous suspending liquids separate the particles according to their effective masses and if the particles are uniform with respect to their densities, the separation proceeds strictly according to the differences in particle size. The analysis of PSD can be realized on the basis of the measurement of the sedimentation velocity during the sedimentation process or from the equilibrium concentration distribution. Nevertheless, it has to be stressed that although centrifugation is, in principle, the separation method, the size-based separation of the particles can be rather complicated because various size particles sediment together and form a complex, superposed concentration gradient in which all size particles are always present in various relative proportions. On the other hand, if the separated particles exhibit nonuniformity in both size and density, size separation can be a rather difficult task.

Sedimentation processes can generate the formation of a density gradient in a complex, multicomponent suspending liquid. The particles suspended in such a density-gradient forming liquid can undergo focusing phenomena and, as a result, they can be separated according to differences in densities. Recent theoretical and experimental findings demonstrate that the size polydispersity in such cases influences the width of the focused zones. Evidently, therefore, if the particles exhibit polydispersity in size and density, the separation is complicated.

Modern theoretical approaches as well as the experimental results demonstrate that sedimentation and focusing can appear together even in a simple suspending liquid because the size polydispersity of the separated particles is itself able to generate the isoperichoric (from Greek: *isos* = equal and *perichoron* = environment) focusing phenomena. It can complicate the use of centrifugation as a simple tool for particle size separation. On the other hand,

although not yet fully mastered and understood, these new approaches offer a challenge for fundamental research and development.

Separation Mechanisms

Sedimentation processes lead to the formation of a concentration gradient. Fickian diffusion, Brownian motion, general entropic tendency and repulsive interactions counterbalance the concentration gradient formed. The sedimentation of an ensemble of particles progresses until an equilibrium concentration distribution is achieved due to the opposed sedimentation and dispersive fluxes. The equilibrium can be described by the differential transport equation:

$$-D \frac{dc}{dx} - Uc = 0$$

where c is the concentration of the sedimenting particles and dc/dx is the concentration gradient formed in the direction of the sedimentation. There exist some limits to the validity of this equation but the details are beyond the scope of this review. The thermodynamic approach defines the equilibrium on the basis of the chemical potential of the sedimenting species μ_i :

$$m_i(1 - v_i\rho(x))\omega^2 x dx - \sum_k \frac{\partial \mu_i}{\partial c_k} dc_k = 0$$

where v_i is the molar volume of the sedimenting species and ω is the angular velocity of the centrifuge rotor. The concentration distribution of uniform-size particles at equilibrium in a homogeneous liquid is exponential. When different but uniform-size colloidal particles sediment separately by forming the exponential concentration distributions, the larger size particles are compressed close to the bottom of the sedimentation cell. This situation is demonstrated in **Figure 13**. On the other hand, the sedimentation of the colloidal particles exhibiting some PSD can lead to very different equilibrium concentration distributions of the particles of different sizes. Larger size particles can be compressed closer to the bottom of the sedimentation cell but they can form focused zones at higher levels as well. These two situations are demonstrated in **Figure 14**.

In the first case shown in **Figure 14**, two exponential concentration distributions corresponding to two different size particulate species are superposed. The lower part of the sedimentation cell contains a higher proportion of larger particles compared with the original mixture and vice versa for the upper part

Figure 13 Schematic representation of the sedimentation of different size particles. Concentration distribution is more compressed to the bottom of the sedimentation cell for larger size particles (left) and centre of gravity of the concentration distribution is closer to the bottom compared with smaller size particles (right).

of the sedimentation cell, and thus size fractionation exists. It is impossible, in principle, to achieve more complete size separation of particles by simple centrifugation.

In the second case shown in Figure 14, larger particles are focused in the density gradient due to the equilibrium exponential concentration distribution of smaller particles. The concentration distribution of larger focused particles approaches a Gaussian distribution function.

The two imaginary cases shown in Figure 14 demonstrate two limit situations which can appear in actual centrifugation experiments in a homogeneous suspending liquid. The focusing phenomenon is, of

course, actively exploited in isopycnic (or more generally isoperichoric) focusing separations of particles. In such cases, a two- or multicomponent liquid is used to form the density gradient and larger particles are separated according to density differences.

The particle-particle interactions which limit the degree of freedom of the particle movements, and whose importance increases with increasing concentration, are the major factors imposing the particular concentration distribution of each sedimenting species of a polydisperse colloidal sample. Consequently, the results of the particle separation performed by any centrifugation method must be carefully evaluated.

Figure 14 Schematic representation of the sedimentation of a mixture of different size particles. The exponential concentration distribution of larger and smaller size particles can be either superposed (left) or larger size particles can be focused within the density gradient formed by the exponential concentration distribution of smaller particles (right).

Figure 15 Isoperichoric focusing of coloured polyaniline particles in the density gradient formed by colourless silica particles in thin-layer isoperichoric focusing (TLIF) cell in a centrifugation experiment.

Applications of Centrifugation

When taking into account the potential and limitations of sedimentation processes, centrifugation can be successfully applied and, in reality, is widely used for the separation of colloidal particles of very different character: inorganic, polymer and biological, and also for the separations of macromolecules. An example of the use of centrifugation is in **Figure 15** which shows the zone of the coloured polyaniline particles focused from a bidisperse mixture with colourless silica particles. This focusing experiment was, indeed, intended not to separate the polyaniline particles from the silica particles of comparable size but to prove the existence of the focusing phenomenon under the given experimental conditions. However, the size separation of the particles using this phenomenon is real.

Electrophoresis

Electrophoresis is a separation technique based on differential transport of electrically charged species. The discovery of electricity was paralleled with an understanding of electrophoretic phenomena and consequently, this separation technique can be considered as classical.

Over the last two decades, all electrophoretic techniques have undergone an explosive growth, especially as concerns the analytical applications of the capillary version of electrophoresis. Nevertheless,

there are only few publications describing the applications of this technique to the separation of charged particles. This can be explained by the fact that separation in electrophoresis is primarily based on differences in electric charge density which is inherently related to the size of the separated particles. As described in the section on HC, the effective size of the particles includes the thickness of the electric double layer which varies with the ionic force of the suspending liquid. This means that whenever the size separation concerns the particles in their natural environment, their effective size includes the electrostatic double layer and separation can be carried out by using electrophoretic transport processes. As the electric charge contains information on the nature of the particle surface, separation by electrophoresis is certainly a useful technique when used appropriately.

The general theory of electrophoretic separations applies to particle separations as well. This has been discussed above in respect to electric FFF. As the applications of electrophoretic techniques to particle separations are still very limited, it is impossible to review this technique as fully as for the other separation methods. Only one recent example, an interesting separation of polyaniline and silica particles, is shown in **Figure 16**.

Figure 16 Electropherograms of the individual polyaniline (PANI) and silica composite particles and of the separated mixture of both obtained by capillary electrophoresis.

Future Development

A search for the historical origins of a scientific discovery is often a difficult task but, with regard to the rapid advances in separation science in general, and of particle size separations in particular, the long-term prediction of progress is almost a 'mission impossible'. However, cautious examination of the state of the art and of potential exigencies concerning particle size separations, allows a few statements about what is likely to happen in the near future to be made.

Further increases in efficiency, resolution and selectivity represent a permanent challenge in particle size separations. An ideal is to separate two particulate species differing by a minimal increment in terms of a 'construction' unit, e.g., one molecule or atom, and not only in terms of 'size increment' which is a rather arbitrary choice.

Increase of the separation speed can be an important factor whenever the separated particles exhibit an evolution in time and it is necessary to capture information on the actual PSD at a given moment. Many biological concepts are approached in this way. The ways to be explored lead to more extensive use of supercritical fluids allowing substantial increase of transport coefficients.

Most recent methods and techniques of particle size separations exploit simple physical and physicochemical principles single driving forces leading to the separation. Coupling of two or more physical fields and field gradients as selective driving forces and their combinations with nonselective transport due to the carrier fluid flow seems to be a recently emerging approach.

Large-scale particle size separations represent important parts of many industrial technologies. The performance of a large-scale separation is often lower in comparison with an essentially identical technique applied under analytical-scale conditions. The optimization of large-scale separation processes in order to approach the performances comparable with analytical-scale conditions. The optimization of large-scale separation processes in order to approach the performances comparable with analytical-scale separations has a potentially important economic impact.

The permanent search for noninvasive conditions in particle size separations is an important field of activity related to fundamental research in the life sciences and also to many important biotechnologies.

These directions of potential future progress in the domain of particle size separations are certainly not exhaustive but they represent an overview of, probably, the most important activities in research and development.

AFFINITY SEPARATION

Affinity Membranes

The rapid development in biotechnology and the large potential of biomolecules for applications in medicine, food industry and other areas, result in an increasing demand for efficient and reliable tools for the purification of proteins, peptides, nucleic acids and other biological substances. This situation is being additionally enforced by the increasing number of recombinant gene products that have arrived on the market or that are currently being investigated, such as insulin, erythropoietin and interferons. The recovery of fragile biomolecules from their host environments requires their particular characteristics to be taken into account for the development of any extraction or separation process. On the other hand, there is a demand for techniques that can easily be scaled up from laboratory to industrial production level.

In this context, the use of affinity methods has the advantage that coarse and fine purification steps are united through the introduction of a specific recognition phenomenon into the separation process. The most widely used method for preparative affinity separation of biomolecules is liquid chromatography on beaded resins (soft gels). Despite the commercial availability of many affinity ligands immobilized on to gel beads for use in column chromatography, there are some drawbacks in a large scale application of these supports. Flow rates and thus performance are limited by the compressibility of the resins and pore diffusion. Because of these intrinsic limitations, other chromatographic techniques, such as perfusion chromatography, or different separation techniques, such as affinity precipitation and affinity phase partitioning, have been suggested as possible alternatives. Another technique that is gaining increasing importance is membrane-based separation. Adsorptive membrane chromatography was introduced as a purification method in the mid 1980s. Microporous membranes have been successfully coupled with biological or biomimetic ligands, yielding affinity membrane chromatography supports. Several of them, with for

example protein A and G, dye or metal chelate ligands, are commercially available. Affinity membrane chromatography is in fact a hybrid technique combining affinity gel chromatography and membrane filtration, with the advantages of the two technologies.

The purpose of the present review is to discuss relevant aspects and developments that are important for the design of an affinity membrane chromatography process, including the choice of the membrane material, coupling chemistry, affinity ligands, membrane configurations, operation modes and scale-up. In a wider sense, membrane-based affinity fractionation also comprises affinity filtration methods where the target molecule binds to an affinity ligand coupled to nanoparticles, which can then be separated by filtration through a membrane. However, this application will not be discussed here in detail.

General Characteristics of Membrane Chromatography

In contrast to chromatographic supports based on beaded resins with dead end pores, membrane chromatographic supports have through-pores and lack interstitial space. Mass transfer is mainly governed by forced convection and pore diffusion is negligible. The observed back-pressures are normally quite low, and high flow rates and thus high throughputs and fast separations become possible without the need for high pressure pumps or equipment. As the association time for an antibody-antigen complex is typically about 1 s or less, but the diffusion of a protein molecule to the centre of a 50 μm porous bead takes tens of seconds, in a membrane support, the low diffusional limitation leads to faster adsorption kinetics and higher throughput efficiency. Little deterioration of the separation efficiency occurs even at elevated flow rates. On the other hand, with affinity membranes the formation of the affinity complex can become the rate-limiting process at high flow rates.

A problem often encountered in membrane chromatography is extra-cartridge back-mixing, which can severely degrade membrane performance. This phenomenon is due to dead volumes outside the membrane, in tubing, fittings and valves, and leads to peak broadening and dilution. It is more pronounced

in membrane chromatography systems compared to conventional columns packed with beaded supports, owing to the larger throughput/bed volume ratio.

Although the specific surface area of membranes is typically only 1% of that of conventional chromatographic resins, microporous membrane systems have high internal surface areas and reasonably high capacities. The open-pore structure of membranes increases the accessibility of affinity ligands and reduces steric hindrance compared to small-pore adsorbents.

Membrane Geometry

Just like filtration membranes in general, affinity membranes can be produced in different configurations, and membrane modules of various geometries are commercially available or have been manufactured in research laboratories (Figure 1).

Flat sheet or disc membranes can be mounted as individual membranes in specially designed cartridges or in commercial ultrafiltration units for use in dead-end filtration mode. This allows for the production of inexpensive single- or multiple-use devices for the rapid adsorption of a target molecule from dilute samples in batch or continuous recycling mode. Car-

tridges are also available that allow for operation in cross-flow filtration mode.

Stacks of flat membrane discs have been employed for affinity membrane chromatography in column-like devices, the main purpose being to increase the adsorption capacity. Another configuration is continuous rod-type membranes which can be directly cast in a chromatographic column. Both types of membrane columns are compatible with conventional high performance liquid chromatography or fast protein liquid chromatography systems and have advantages over columns packed with beaded resins, as described above. Being highly porous with a mean pore diameter of 0.1–10 μm , they allow for efficient separations even at high flow rates.

If the target molecule is to be recovered from complex feed solutions such as cell homogenates or blood plasma, or from solutions containing high molecular mass additives such as antifoam agents or even particulate material, the use of membranes in dead-end filtration mode is often impossible due to membrane fouling. A remedy to this problem is the operation in cross-flow filtration mode where the build-up of a polarization layer at the membrane surface is avoided or diminished. Hollow-fibre membranes are well adapted for such applications. They are usually

Figure 1 Different geometries of affinity membranes. (A) Flat sheet; (B) stack of flat discs; (C) hollow fibre; (D) spiral-wound flat sheet; (E) continuous rod. The arrows indicate flow directions. (Adapted from *Journal of Chromatography* 702, Roper DK and Lightfoot EN, Separation of biomolecules using adsorptive membranes, pp. 3–26, Copyright 1995, with permission from Elsevier Science.)

mounted as bundles in tubular cartridges. Another configuration are flat-sheet membranes that are spiral-wound around a cylindrical core. Both systems have the advantage of high surface area/cartridge volume ratios and high operational capacities.

Membrane Material, Activation and Ligand Coupling

Membrane Material

Due to the specific properties of biomolecules, the membrane materials to be used for their separation should ideally possess the following characteristics:

- **Macroporosity:** This will allow biomolecules to cross the membrane and to access the affinity sites.
- **Hydrophilicity:** Using hydrophilic supports, non-specific adsorption by hydrophobic interactions and denaturation of biomolecules can be avoided.
- **Presence of functional groups:** These are required for the coupling of an affinity ligand.
- **Chemical and physical stability:** The material has to withstand the sometimes harsh conditions during derivatization, operation and regeneration.
- **Biocompatibility:** This is particularly important if the membranes are used in extracorporeal devices, for example for blood treatment.
- **Large surface area relative to membrane volume:** This will allow for the construction of small, integrated devices with high operational capacities.

Cellulose and cellulose acetate were among the first materials that have been used for affinity membrane preparation. They are hydrophilic and biocompatible, and due to the presence of hydroxyl groups, ligand coupling can be easily achieved using for example CNBr or carbonyldiimidazole activation. In order to improve the mechanical and chemical stability of cellulose membranes, chemical cross-linking with epichlorohydrin is sometimes carried out. Cellulose membranes normally have a rather small pore size, resulting in a high pressure drop. Attempts to produce membranes with larger pores using coarse cellulose fibres have resulted in a less uniform membrane structure.

Polysulfone is another suitable membrane material which has good film-forming properties. It is of sufficient physical, chemical and biological stability, and ligands can be coupled after chloromethylation-amination or acrylation-amination.

Microporous polyamide (nylon) membranes have also been used for the preparation of affinity

membranes. This material is mechanically stable and has a rather narrow pore size distribution. It contains only a small number of terminal amino groups for ligand coupling, which can, however, be increased by partial hydrolysis of the amide functions.

A suitable membrane material is polyvinyl alcohol, in particular because of its hydrophilicity and biocompatibility. Poly(ethylene-co-vinyl alcohol), which has a somewhat higher chemical stability, has also been used. Both materials contain hydroxyl groups and can be activated by the CNBr method, allowing immobilization of affinity ligands having an amino function. Ligands can also be coupled using epichlorohydrine or butanediol diglycidyl ether-activation.

Other materials that have been used for affinity membranes are poly(methyl methacrylate), poly(hydroxyethyl dimethacrylate), polycaprolactam, poly(vinylidene difluoride), poly(ether-urethane-urea) and silica glass. Table 1 shows a list of membrane materials and the appropriate ligand-coupling chemistries.

Composite Membranes

The main difficulty when choosing a membrane for affinity separation of biomolecules is sometimes to find a material that fulfils several or all of the above-mentioned requirements. For example, a chemically stable material might be too hydrophobic and lead to nonspecific and irreversible adsorption of the protein to be separated, whereas a hydrophilic material that is compatible with the fragile protein molecules might not withstand the conditions required for ligand coupling and for regeneration and sterilization of the membrane. Therefore, the choice of a membrane material will sometimes be a compromise. The use of a composite membrane consisting of two or more different materials may often be the only solution to a particular separation problem. This approach consists of the grafting of hydrophilic polymers on to a chemically and mechanically stable microporous membrane. The result is an increased biocompatibility as well as the introduction of suitable functional groups for ligand coupling. One example is the radiation-induced graft polymerization of 2-hydroxyethyl methacrylate or glycidyl methacrylate on to a polyethylene hollow fibre membrane. This increases the hydrophilicity of the material and introduces active hydroxyl groups or reactive epoxy groups.

Activation and Ligand Coupling

From a practical point of view, apart from the chemical compatibility of the membrane material with the activation and coupling solutions, an important

Table 1 Membrane materials and possible chemistries for ligand coupling

<i>Membrane material</i>	<i>Coupling chemistries</i>	<i>Ligand functional group</i>
Cellulose, cellulose diacetate	Epichlorohydrin, butanediol diglycidyl ether	Amino, (hydroxyl)
	Carbonyldiimidazole	Amino, hydroxyl
	CNBr	Amino
	Anhydride	Amino
	Hydrazide	Amino
Polysulfone	Acrylation-amination, chloromethylation-amination	Cl ⁻ (aromatic)
Polyamide	Ethylene glycol diglycidyl ether	Amino, (hydroxyl)
	Glutaraldehyde (Schiff base)	Amino, amido
	Divinyl sulfone	Hydroxyl
	2-Fluoro-1-methylpyridinium toluene-4-sulfonate	Primary amino
	Butanediol diglycidyl ether	Amino, (hydroxyl)
Poly(vinyl alcohol), poly(ethylene vinyl alcohol) Electrostatically spun poly(ether-urethane-urea)	Formaldehyde	Hydroxyl
	Epichlorohydrin, butanediol diglycidyl ether	Amino, (hydroxyl)
	Carbonyldiimidazole	Amino, hydroxyl
	CNBr	Amino
	Carbonyldiimidazole	Amino, hydroxyl
Glass	Glycidyloxypropyl trimethoxysilane	Amino, (hydroxyl)
	Aminopropyltrimethoxysilane	Carboxyl

aspect is that these solutions need to access the pores of the membrane. In many cases it will therefore be necessary to do the activation in dynamic mode, that is, by forced convection. This is especially important if the membrane material is hydrophilic and the activation and coupling solutions are based on nonpolar solvents, since in that case the wettability of the membrane by the solutions will be low.

Spacer Arms

Occasionally, affinity membranes may show poor performance if the ligand, and in particular a small ligand, is coupled directly to the membrane. This is often due to a low steric availability of the ligand, a problem that can be overcome by the use of a suitable spacer arm. In that way, the ligand accessibility for the molecule to be separated is improved, resulting in an increase in membrane-binding capacity. For example, 1,6-diminohehexane or 6-aminohehexanoic acid are often used as spacers. In other cases, the coupling method itself provides a spacer, as is the case with butanediol diglycidyl ether. If composite membranes with crafted flexible copolymer chains are used, spacer arms are not normally required.

Affinity Ligands

Biological Ligands

Just like other affinity separation techniques, affinity membrane technology uses biomolecules as the affinity ligands, thus taking advantage of the specificity of biological recognition. One of the most

common applications is the use of immobilized monoclonal antibodies against natural or recombinant proteins as the ligand for immunoaffinity separation. Another important example are membranes with covalently coupled protein A or protein G for immunoglobulin purification from plasma, serum or cell culture supernatants. Immobilized lectines have been used for the purification of glycoproteins. The use of inhibitors or coenzymes for the purification of enzymes is also possible. Although biomolecules are widely used as ligands for their selectivity, they do have drawbacks. Their poor stability and sometimes high price can make them problematic for use in large scale affinity separation. Drastic conditions are often necessary for elution of the ligate, for example with high affinity antibody-antigen interactions. This can lead to partial inactivation of the molecule to be purified. Ligand denaturation and inactivation, in particular with protein ligands, can occur during regeneration and sterilization of the membrane. Another important issue is the possible leaching of the affinity ligand, leading to a contamination of the final product, which is particularly problematic if the product is to be used in medical applications.

Pseudobiospecific Ligands

An alternative approach involves the use of biomimetic or pseudobiospecific affinity ligands. These are usually smaller and simpler molecules with higher chemical and physical stability than biomolecules. The working principle of pseudobiospecific ligands relies on the complementarity of

structural features of ligand and ligate rather than on a biological function, whereas biomimetic ligands have a certain structural resemblance with a biological ligand. For example, textile dyes can be used for the separation of proteins, and in particular Cibacron Blue F3GA has been employed as ligand in affinity membranes for the purification of dehydrogenases, since it often binds specifically to the nucleotide-binding site. Other dyes may adsorb proteins less specifically, but by selection of the right dye (a large number of different dyes is currently available) and the appropriate adsorption and elution conditions, highly efficient separations can be obtained.

Proteins carrying accessible histidine residues on their surface have been shown to have affinity for transition metal-chelate ligands. Typical examples are the iminodiacetate-copper(II) complex (IDA-Cu(II)) and the nitrilotriacetate-nickel (NTA-Ni(II)) ligand widely used for purification of recombinant proteins with genetically attached poly-His tails.

A third group are amino acids such as phenylalanine, tryptophane and histidine. Being the least selective, they have nevertheless been successfully employed for protein purification. However, fine-tuned adsorption and elution conditions are necessary to achieve efficient separation. Mention should also be made of the thiophilic affinity system that has been used with affinity membranes. It is based on the salt-promoted adsorption of proteins via thiophilic regions (containing aromatic amino acids) on to sulfone or thioether-containing heteroaliphatic or aromatic ligands.

Molecularly Imprinted Membranes

A completely different approach for the preparation of affinity membranes is the use of molecularly imprinted polymeric materials. These are produced by polymerization of functional and cross-linking monomers in the presence of the target molecule (the molecule to be separated later), which acts as a molecular template. In this way, binding sites are introduced in the polymer that are complementary in shape and functionality to the target molecule, and that often have specificities comparable to those of antibodies. At the same time, the cross-linked polymeric material provides a porous, chemically and physically very stable support. Even though the technology is in principle applicable to larger biomolecules such as proteins, it has mainly been used for the separation of small molecules like amino acids and peptides. The molecular imprinting technique is reviewed in more detail elsewhere.

Scale-up

Process scale-up tends to be rather easy in adsorptive membrane chromatography, at least compared to the use of conventional beaded resins as the chromatographic support. It has been demonstrated that the diameter of a stack of disc membranes can be increased by up to one order of magnitude and more, with the dynamic capacity remaining constant. This allows for the processing of considerably larger sample volumes at higher flow rates. With radial flow membranes, when both the height and diameter of the cartridge were increased and the flow rate adjusted proportionally to the increased cartridge volume, the apparent specific capacity decreased only slightly.

Applications

Several different applications of affinity membranes have been described. Typical examples of their use for the separation and purification of biomolecules are shown in Table 2.

The most common application is the separation and purification of biomolecules and especially proteins for large scale production. A common example is the separation of immunoglobulins from blood serum or plasma or from cell culture supernatants. Hollow-fibre cartridges with immobilized protein A or pseudobiospecific ligands have been used for this purpose. Figure 2 shows a chromatogram from a case study of immunoglobulin G separation from human plasma using a small, developmental-scale (28 cm² surface area) poly(ethylene-co-vinyl alcohol) hollow-fibre membrane cartridge. The pseudobiospecific affinity ligand histidine was immobilized on to the membrane after activation with butanediol diglycidyl ether, thus introducing a spacer arm. Serum was injected 10-fold diluted in cross-flow filtration mode. Weakly retained and entrapped proteins were then removed by washing the lumen and the outer shell of the fibres, as well as the pores in back-flushing mode. Adsorbed immunoglobulins were subsequently eluted with a buffered solution of 0.4 mol L⁻¹ NaCl in back-flushing mode. The eluted fraction contained 93% immunoglobulins (82% IgG, 10.8% IgM). The dynamic binding capacity of the membrane for immunoglobulin G was determined to be 1.9 g m⁻². The process could then be scaled up by using a cartridge with 1 m² membrane surface area.

A related application is the final polishing of an already pure product. For example, the removal of bacterial endotoxins from contaminated solutions of monoclonal antibodies has been demonstrated using membrane-bound pseudobiospecific ligands.

Table 2 Examples for the use of affinity membranes for isolation and purification of biomolecules

<i>Isolated substance</i>	<i>Affinity ligand</i>	<i>Membrane material</i>	<i>Configuration</i>	<i>Application</i>
Human serum amyloid protein	Anti-hSAP Ab (polyclonal)	Cellulose	Flat sheets	Extracorporeal circuit, removal of amyloid from blood
Heparin	Poly-L-lysine	Cellulose diacetate poly(ethylene-co-vinyl alcohol), coated polyethylene	Hollow fibres	Extracorporeal circuit, removal of heparin from blood
Human IgG	Recombinant protein A	Poly(caprolactam) Modified poly(caprolactam) Polysulfone-coated hydroxyethyl cellulose	Hollow fibres Hollow fibres, flat sheet Hollow fibres	Purification
Recombinant protein G	Human IgG	Glycidyl methacrylate-co-ethylene dimethacrylate	Discs	Purification
Trypsin (porcine)	Soybean trypsin inhibitor	Modified cellulose	Spiral wound sheet (radial flow)	Purification
Glucose-6-phosphate dehydrogenase	Cibacron blue	Nylon	Stack of flat sheets	Purification from clarified yeast homogenate
Human IgG	Histidine	Poly(ethylene-co-vinyl alcohol)	Hollow fibres	Purification from blood plasma and serum
Autoantibodies				Removal from blood plasma in extracorporeal circuit
Lysozyme, cytochrome c, ribonuclease A	IDA-Cu ²⁺	Glass	Hollow fibres	Purification

Figure 2 Separation of immunoglobulins from human serum using a poly(ethylene-co-vinyl alcohol) hollow-fibre cartridge with immobilized L-histidine. (a) Immunoglobulin adsorption in cross-flow filtration mode; (b) lumen wash; (c) shell wash; (d) back-flush wash; (e) back-flush elution. (Adapted from *Journal of Membrane Science* 117, Bueno SMA, Legallais C, Haupt K and Vijayalakshmi MA, Experimental kinetic aspects of hollow-fiber membrane-based pseudobioaffinity filtration: Process for IgG separation from human plasma, pp. 45–56, Copyright 1996, with permission from Elsevier Science.)

Affinity membranes have also been suggested for use in extracorporeal circuits, for the removal of toxic substances such as certain metabolites or antibodies from blood. For example, exogenous human serum amyloid P component, a substance associated with Alzheimer's disease, has been removed from whole rat blood in an extracorporeal circulation system. This model system used a polyclonal antibody coupled to cellulose flat-sheet membranes. The biocompatibility of the membrane was also demonstrated. A similar application is the removal of autoantibodies from human plasma, using membrane-bound affinity ligands in extracorporeal circuits.

Apart from preparative applications, small cartridges with membrane discs or continuous membrane rods should be useful for analytical-scale separations and affinity solid-phase extraction, for example for immunoextraction.

Conclusions

Affinity membrane separation techniques combine the specificity of affinity adsorption with the unique hydrodynamic characteristics of porous membranes. They provide low pressure separation systems which are easy to scale up and ideal for the processing of large volumes of potentially viscous feed solutions (e.g. microbial broth, bacterial cell extract, conditioned media) often involved in the production of recombinant proteins. The additional microfiltration effect of membranes allows for the processing even of unclarified, particle-containing feed solutions. The high performance of this separation technique is due to the presence of throughpores and the absence of diffusional limitations; mass transfer is mainly governed by forced convection. Affinity membranes are used in applications such as purification of biomolecules, final product polishing, removal of unwanted substances from patients' blood in extracorporeal circuits, but also

for smaller scale analytical separations. Biological affinity ligands and biomimetic or pseudobiospecific ligands are currently employed, as well as different membrane configurations such as flat sheets, hollow fibres or continuous rods. The technology is now in the process of being adapted more and more for large scale industrial separation and purification.

Affinity Partitioning in Aqueous Two-Phase Systems

G. Johansson, Center for Chemistry and Chemical Engineering, Lund University, Lund, Sweden

Copyright © 2000 Academic Press

Aqueous Two-phase Systems in General

The division of water into non-miscible liquid layers (phases) by addition of two polymers has led to the

remarkable possibility of being able to partition proteins and other cell components between phases of nearly the same hydrophilicity. Proteins can be separated by partitioning if they have unequal distribution between the phases, i.e. when their partition coefficients, K (the concentration in top phase divided by the concentration in bottom phase), differ. Usually the difference in the K value of many proteins is not very large and then repeated extractions have to be carried out to get a reasonable

purification. If, however, the protein of interest (the target protein) has a very high K value and is mainly in the upper phase and all the contaminating proteins have very low K values so that they are in the bottom phase, an effective and selective extraction can be obtained in a single or a few partitioning steps. This type of partitioning has been made possible by using affinity ligands restricted to the upper phase.

The composition of the phases when two polymers like dextran and polyethylene glycol (PEG) are dissolved together in water depends on the amount of the polymers and their molecular weights. The concentration of the polymers in two phases of a given system can be found in the phase diagram for the temperature being used. A typical phase diagram is shown in Figure 1.

The line that connects the points in the diagram representing the compositions of the top and bottom phases of a system is called the tie-line. Each system with a total composition (percentage of each polymer) belonging to the same tie-line will have the same phase compositions. The smaller the tie-line, the more similar are the two phases in their composition. The greatest difference in composition of the top and bottom phases is therefore obtained by using high polymer concentrations.

The partitioning of proteins and also of membranes and particles depends on the polymer concentration of the system. The K value of a protein will be the same for all systems belonging to the same tie-line.

Figure 1 Phase diagram for the system dextran 500 (500 000 Da), PEG 8000 (8000 Da), and water at 23°C. Polymer compositions above the curved line (bimodal curve) give two liquid phases. All two-phase systems with their total composition on the same straight line (tie-line) have the same composition of top phase (▲) and bottom phase (■). The systems differ in phase volume ratio depending on their position on the tie-line. The indicated total compositions (●) give systems with more top phase (three to five times) than bottom phase.

The partition coefficient will, in most cases, decrease with the length of the tie-line, i.e. by using higher concentrations of the two polymers the material will accumulate more in the lower phase. Another way to affect the partitioning of proteins is by addition of salts to the system. Their effect depends on the type of cation and anion introduced with the salt. Negatively charged proteins show increasing K values when the cation is changed in the series:

For the anion the partition coefficient increases in the following order:

The highest K value of negatively charged proteins will then be obtained with the salt tetrabutylammonium hydrogenphosphate and the lowest K value with potassium perchlorate. Proteins with zero net charge (at their isoelectric points) are not affected by salts while positively charged proteins behave in an opposite manner to the negatively charged ones. For a number of proteins the log K values are nearly a linear function of their net charge (Figure 2).

Affinity Partitioning

The principle of affinity partitioning is to localize an affinity ligand in one phase to make it attract ligand-binding proteins. Since the phase-forming polymers are in each phase, either one can be used as ligand carrier. The standard system for affinity partitioning has been the one composed of dextran, PEG and water. Dextran is then used for localizing the ligand in the bottom phase while PEG can be used to concentrate the ligand to the top phase. PEG has often been chosen as ligand carrier because bulk proteins can be effectively partitioned into the dextran-rich lower phase by using high concentrations of polymers and a suitable salt. Thus, the target protein is extracted towards the upper phase leaving contaminating proteins in the bottom phase. PEG has two reactive groups (the terminal hydroxyl groups) which can be used as points of ligand attachment. In many cases only one ligand molecule is attached per PEG molecule. If the ligand is a large molecule (e.g. an antibody protein) several PEG chains may be attached to the one ligand molecule. Normally, only a fraction (1–10%) of the PEG in the two-phase system has to carry the ligand to reach maximal extraction efficiency. The more extreme the partitioning of a ligand-polymer is toward a phase the more effective it will be in extracting a ligand-binding protein into this phase. The partitioning of

Figure 2 Log K of the protein ribonuclease-A as function of its net charge, Z , in a two-phase systems containing KSCN (\circ , 100 mM), KCl (\bullet , 100 mM), or K_2SO_4 (\square , 50 mM). System compositions: (A) 6.2%w/w dextran 500 and 4.4%w/w PEG 8000; (B) 9.8%w/w dextran 500 and 7.0%w/w PEG 8000. Protein concentration, 2 g L^{-1} . Temperature, 20°C . (Reprinted from Johansson G (1984) *Molecular Cell Biochemistry* 4: 169–180, with permission from Elsevier Science.)

the ligand–polymer should be in the same range as the non-derivatized polymer but it may, in some cases, be more extreme. The higher the polymer concentrations are in the system, i.e. the longer the tie-line of the system, the more extreme is the partitioning of PEG to the top phase and dextran to the bottom phase. This can be expressed by the partition coefficients of the two polymers:

$$K_{\text{PEG}} = \frac{c_{\text{PEG,top}}}{c_{\text{PEG,bottom}}} \quad \text{and} \quad K_{\text{dextran}} = \frac{c_{\text{dextran,top}}}{c_{\text{dextran,bottom}}}$$

where c is the respective polymer concentration in top or bottom phase. Table 1 shows the K_{PEG} and K_{dextran} values for systems containing PEG 8000 and dextran 500. Dextran has a more extreme value of K than PEG, i.e. $K_{\text{PEG}} < 1/K_{\text{dextran}}$. Dextran should therefore, in principle, be a better ligand carrier than PEG. The concentration ratio for dextran is roughly the square of the ratio for PEG in the same system.

A Simple Theory for Affinity Partitioning

A basic theory for affinity partitioning was elaborated by Flanagan and Barondes in 1975. They analysed the combined binding and partition equilibria taking place in and between the two phases, respectively (Figure 3).

In this scheme the ligand–PEG(L), the free protein (P) and the two complexes (PL and PL_2) have each their own partition coefficient (K_L , K_P , K_{PL} and K_{PL_2}). Furthermore, in both phases association between protein and ligand–PEG takes place which can be described by the association constants:

$$K_1 = [PL]/([P][L]) \quad \text{and} \quad K_2 = [PL_2]/([PL][L])$$

one set for each phase.

A total association constant for the equilibrium:

can also be used: $K_{\text{tot}} = K_1 K_2$.

Table 1 Partition coefficients of PEG (K_{PEG}) and dextran (K_{dextran}) and their logarithmic values (log) at various tie-line lengths of the system in Figure 1

Tie-line length (polymer concentration scale)	K_{PEG}	K_{dextran}	$\log K_{\text{PEG}}$	$\log K_{\text{dextran}}$
8.0	1.9	0.25	0.28	− 0.60
14.2	6.7	0.023	0.83	− 1.64
17.4	12	0.0088	1.08	− 2.06
25.6	35	0.0022	1.54	− 2.66
31	46	0.0004	1.66	− 3.4
35	61	0.0001	1.79	− 4.0

Figure 3 Scheme for affinity partitioning of a protein (P) with two binding sites for a ligand attached to PEG (L). The complexes between protein and ligand-PEG are PL and PL₂, respectively.

The association constants, K_{tot} , K_1 and K_2 may differ between the two phases. According to Flanagan and Barondes, the measured $\log K$ value of a protein, $\log K_{\text{protein}}$, will, theoretically, give rise to a saturation curve when plotted versus the concentration of polymer-bound ligand in the system (compare Figure 4).

The $\log K_{\text{protein}}$ value reaches a plateau when the concentration of L-PEG is so high that practically all the protein is present as the fully saturated complex PL₂. The protein molecule is then surrounded by two PEG chains and outwardly shows a PEG atmosphere.

Figure 4 Increase in the logarithmic partition coefficient of phosphofructokinase (PFK) from bakers' yeast as function of the concentration of Cibacron blue F3G-A PEG (Cb-PEG). System composition: 7%w/w dextran 500, 5%w/w PEG 8000 including Cb-PEG, 50 mM sodium phosphate buffer pH 7.0, 0.5 mM EDTA, 5 mM 2-mercaptoethanol and 4 nkat g⁻¹ enzyme. Temperature, 0°C. The inverse plot inserted is used to determine the $\Delta \log K_{\text{max}}$.

The maximum partition coefficient of protein, $\hat{K}_{\text{protein}} (= K_{\text{PL}_2})$, is related to K_p , K_L and the K values via the following equations:

$$\hat{K}_{\text{protein}} = K_p K_L^2 \frac{K_{1,T} K_{2,T}}{K_{1,B} K_{2,B}}$$

or:

$$\hat{K}_{\text{protein}} = K_p K_L^2 \frac{K_{\text{tot},T}}{K_{\text{tot},B}}$$

The maximum increase in the logarithmic partition coefficient, $\Delta \log K_{\text{max}}$, is consequently given by:

$$\begin{aligned} \Delta \log K_{\text{max}} &= \log \frac{\hat{K}_{\text{protein}}}{K_p} \\ &= 2 \log K_L + \log K_{\text{tot},T} - \log K_{\text{tot},B} \end{aligned}$$

If $K_{\text{tot},T} = K_{\text{tot},B}$ then $\Delta \log K_{\text{max}} = 2 \log K_L$.

From the values in Table 1 it may therefore be assumed that for proteins with two binding sites $\Delta \log K_{\text{max}}$ can be as high as 3.57 (an increase of 3700 times in K) when PEG is used as ligand carrier with $K_L = 61$. If dextran is used as carrier, in the same system, the $\Delta \log K_{\text{max}}$ should theoretically be around -8 corresponding to a one hundred million times increase in the affinity of the protein for the lower phase if K_L is 0.0001. A higher number of binding sites (n) should then give strongly increasing $\Delta \log K_{\text{max}}$ values with $\Delta \log K_{\text{max}} = n \log K_L$. However, the affinity extraction effect may be reduced by a reduction of individual binding strengths.

Experimental Results

The extraction curves of a protein, here exemplified with phosphofructokinase (PFK) from baker's yeast, using Cibacron Blue F3G-A PEG, closely follows the predicted behaviour (Figure 4). The inverse plot makes it possible to estimate the value of $\Delta \log K_{\text{max}}$.

The dependence of $\Delta \log K_{\text{max}}$ of PFK on the polymer concentration is shown in Figure 5. Increasing concentration of polymers corresponds to longer tie-line length (and greater K_L value) and this makes the affinity partitioning, measured as $\Delta \log K_{\text{max}}$, more efficient.

In addition to the concentration of polymers and ligand-PEG the actual K_{protein} obtained also depends on pH value, the salt added to the system and the temperature. Two salts which have little or no effect on the affinity partitioning are phosphates and acetates in concentrations up to 50 mM. In the case of PEG the $\Delta \log K_{\text{max}}$ is reduced with increasing temperature.

Figure 5 (A) $\log K$ of phosphofructokinase from bakers' yeast as function of the tie-line length, expressed in the polymer concentration scale, in systems with an excess of Cibacron blue F3G-A PEG (Cb-PEG) (●), 3% of total PEG; or without Cb-PEG (Δ). (B) $\Delta \log K_{\max}$ (○) and $\log K_L$ (■) as function of the tie-line length. System composition: dextran 500 and PEG 8000 (including Cb-PEG) in weight ratio 1.5:1, 50 mM sodium phosphate buffer pH 7.0, 0.5 mM EDTA, 5 mM 2-mercaptoethanol, and 4 nkat g^{-1} enzyme. Temperature, 0°C.

The detachment of ligand from the enzyme can be achieved either by using a high concentration of salt or by the addition of an excess of free ligand. For PFK the addition of adenosine triphosphate (ATP) to the

system containing ligand-PEG strongly reduces the partition coefficient of the enzyme (Figure 6).

Types of Affinity Ligands Used

A number of affinity ligands have been used and some are presented in Table 2. The attachment of ligand to polymers and the purification of the ligand-polymer differs from case to case. Some ligands such as reactive textile dyes can be bound directly to PEG and to dextran in water solution of high pH. Other ligands are introduced by reactions in organic solvent, such as the attachment of acyl groups to PEG by reaction with acyl chloride in toluene. PEG may also be transformed into a more reactive form such as bromo-PEG, tosyl-PEG or tresyl-PEG. Some reaction pathways are shown in Figure 7. A number

of methods to synthesize polymer derivatives have been published by Harris.

Preparative Extractions

The following steps may be useful for a high degree of purification by affinity partitioning.

1. Pre-extraction in a system without ligand-PEG to remove proteins with relatively high partition coefficients. The target protein stays in the bottom phase by adjusting the choice of polymer concentration, salt and pH.
2. Affinity partitioning is carried out by changing the top phase for one containing ligand-PEG. The target protein will now be in the top phase.
3. Washing the top phase with bottom phase to remove co-extracted proteins.
4. 'Stripping' of protein from the affinity ligand by addition of highly concentrated phosphate solution (50%w/w) to the separated upper phase. This generates a PEG-salt two-phase system with PEG and ligand-PEG in the top phase and target protein in the salt-rich bottom phase. An alternative stripping procedure can be carried out by adding a new pure dextran phase to the recovered top phase and supplying the system with free

ligand. In this case the target protein will be collected in the lower phase.

For each step the number of extractions and the most suitable volume ratios for yield and purity can be optimized. The procedure is summarized in **Figure 8**.

The yield in the top phase, Y_T , can be calculated from the K value of target protein and the volumes of top and bottom phase, V_T and V_B , respectively, using the following equation:

$$Y_T (\%) = \frac{100}{1 + V_B/(V_T K)}$$

and the yield in the bottom phase, Y_B

$$Y_B (\%) = \frac{100}{1 + V_T K/V_B}$$

A considerable concentration of the target protein, in addition to purification, can be achieved by choosing an extreme volume ratio with a small collecting phase.

An example of preparative extraction of an enzyme by applying the method given in **Figure 8** is the purification of lactate dehydrogenase (LDH) using a PEG-bound textile dye. Crude extract of pig muscle,

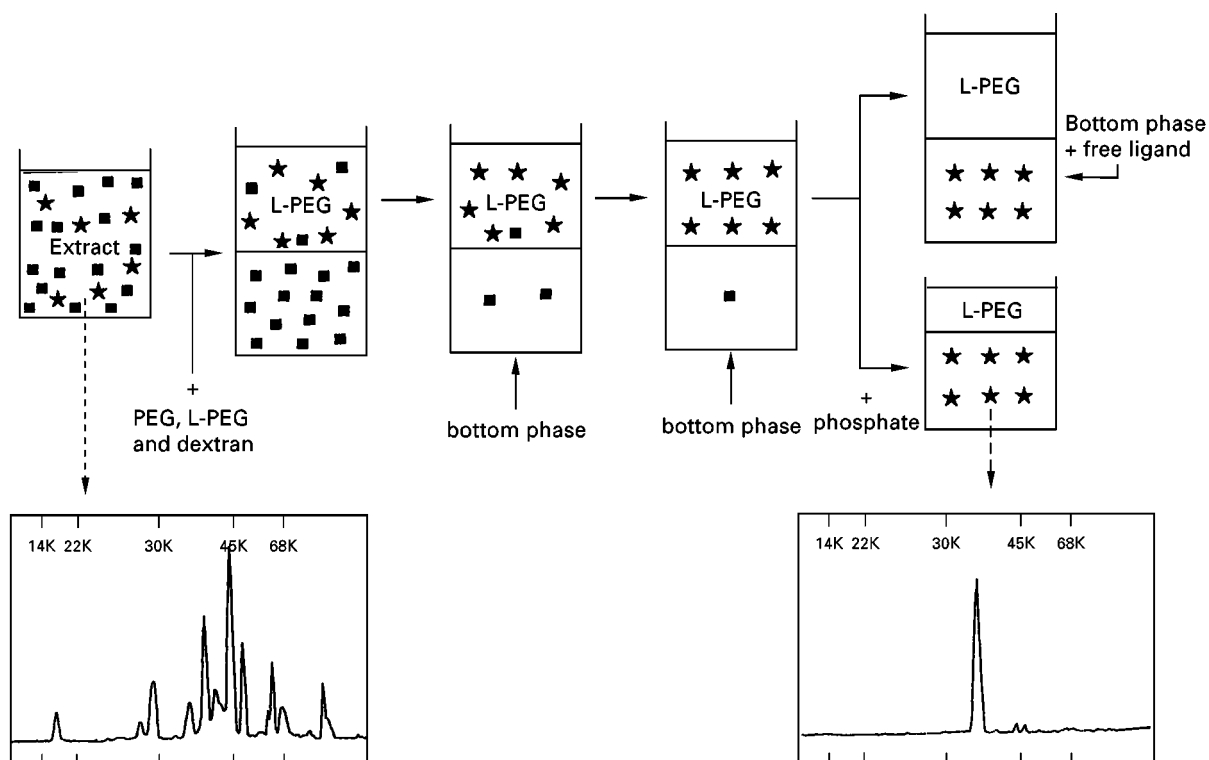

Figure 8 Scheme for the purification of an enzyme (★) from contaminating proteins (■) by using four partitioning steps and PEG-dextran two-phase systems with PEG-bound ligand. This approach has been used for the purification of lactate dehydrogenase (LDH) from meat juice by affinity partitioning with Procion yellow HE-3G PEG. The inserted SDS-PAGE patterns of the original meat extract and the final product (obtained in the phosphate-rich phase) show the removal of contaminating proteins. Recovery of enzyme = 79%. System composition: 10% w/w dextran 500 and 7.1% w/w PEG 8000 including 1% Procion yellow HE-3G PEG (of total PEG), 50 mM sodium phosphate buffer pH 7.9, and 25% w/w muscle extract. Temperature, 0°C. (Reprinted from Johansson G and Joelsson M (1986) *Applied Biochemistry Biotechnology* 13: 15–27, with permission from Elsevier Science.)

cleared by centrifugation, is mixed with PEG, dextran and Procion yellow HE-3G PEG. After the first partitioning the top phase is washed twice with pure lower phases and then it is mixed with a 50% w/w salt solution (25% NaH_2PO_4 + 25% $\text{Na}_2\text{HPO}_4 \cdot \text{H}_2\text{O}$). The protein content of the final product in the salt-rich phase compared with that of the initial extract is demonstrated by the polypeptide pattern in sodium dodecyl sulfate-polyacryl amide gel electrophoresis (SDS-PAGE) shown in Figure 8. The

L-PEG (and PEG) recovered in the final top phase is $\geq 95\%$ of the initially introduced amount.

Purification of PFK in combination with a precipitation step with PEG before the affinity partitioning step greatly reduces the original volume of enzyme solution. The extraction included both pre-extraction and washing steps. The final polishing of the enzyme was made by ion exchanger and desalting with gel chromatography. The results can be seen in Table 3.

Table 3 Purification of phosphofructokinase from 1 kg (wet weight) bakers' yeast

Purification step	Volume (ml)	Total activity (U)	Total protein (mg)	Specific activity (U/mg)	Purification factor	Yield (%)	Proteolytic activity ^a (%)

^aIn the presence of the protease inhibitor phenylmethylsulfonyl fluoride.

Figure 9 Affinity extraction into the top phase, by using increasing amount of PEG-bound ligand, calculated for an enzyme with the mole mass $100\,000\text{ g mol}^{-1}$, containing two binding sites for the ligand, and with $K_p = 0.01$. The value for the partition coefficient, K_L , of the ligand is 100. The association constant, K , for each site is 10^{-6} M^{-1} (○, □) or 10^{-4} M^{-1} (+). The concentration of enzyme: 10 (○), 100 (□, +) and 500 g L^{-1} (Δ).

The effectiveness of affinity partitioning depends on the binding strength between ligand and protein. Good extraction is obtained with association constants of 10^4 M^{-1} or more (Figure 9). The capacity, based on the amount of ligand in the system, is in the range of several hundred grams of protein per kilogram of system. Affinity extractions with 150 g of protein per kilogram of system have been carried out, and in these cases the two-phase systems strongly change the phase volume ratio while the bulk protein acts as a phase-forming component. In systems with high protein concentration the amount of dextran can be reduced or even excluded.

Countercurrent Distribution

A convenient way of multiextraction is countercurrent distribution (CCD). Here a number of top phases are sequentially moved over a set of bottom phases and equilibration takes place after each transfer. The process can be seen as a step-wise chromatography. The original two-phase system, number 0, contains the sample and after that a number (n) of transfers have been carried out $n + 1$ systems are obtained and the various proteins in the sample are distributed along the CCD train. The CCD process is visualized in Figure 10(A).

The distribution of a pure substance can be calculated from the K value of the substance and the volumes of the phases, V_T and V_B . Assuming that all of the top phase volume is mobile and all bottom phase stationary, the fractional amount, $T_{n,i}$, in tube number i (i goes from 0 to n) after n transfers will be given by:

$$T_{n,i} = \frac{n!}{i! (n-i)!} \frac{G^i}{(1+G)^n}$$

This makes it possible to calculate the theoretical curve for a substance and to make comparisons with the experimental distribution curve. Such an analysis may reveal the presence of several components even if they are not separated into discrete peaks. Figure 10(B) shows an example of a CCD of a yeast extract using PEG-bound affinity ligands. The distribution of a number of enzyme activities has been traced.

Use of Dextran as a Ligand Carrier

Dextrans of the molecular weights normally used (40 000 and 500 000 Da) contain many thousands of reactive hydroxyl groups per molecule. The affinity partitioning effect achieved by introducing

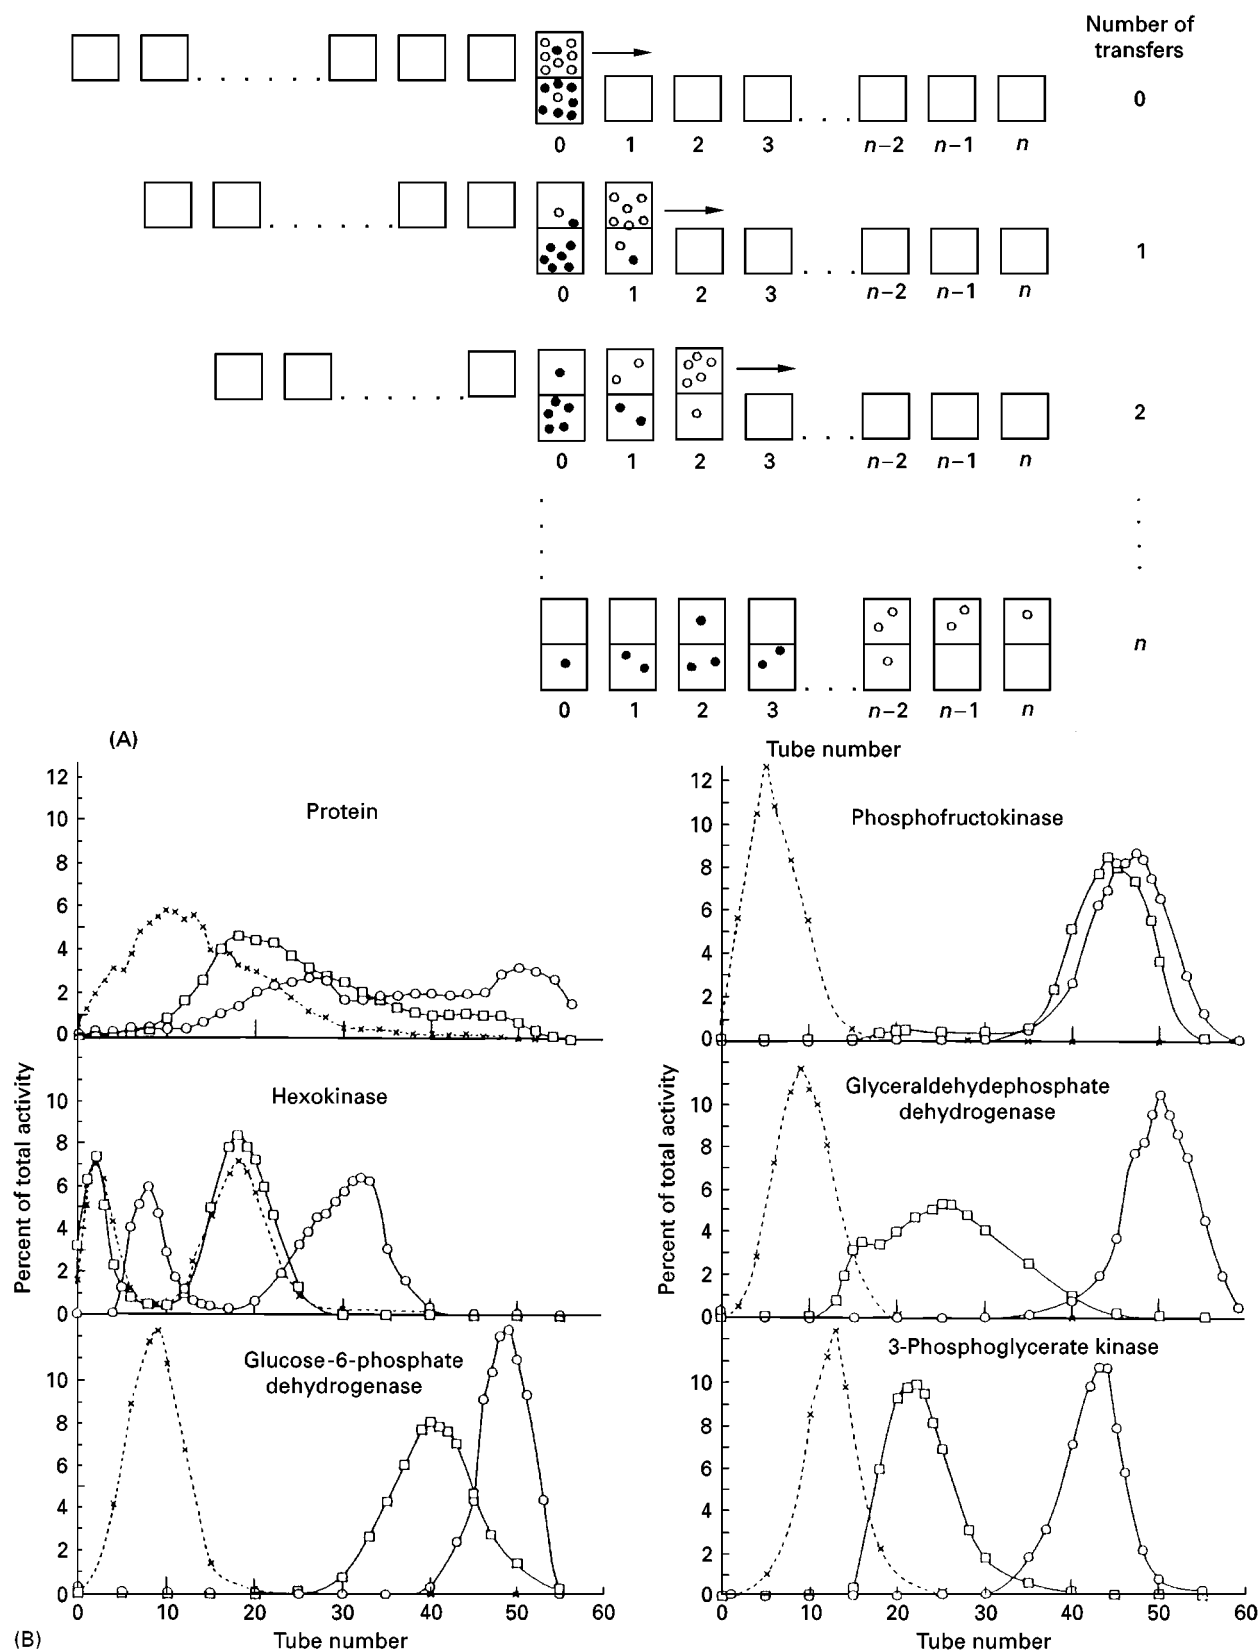

Figure 10 (A) Scheme of the countercurrent distribution (CCD) process. (Reprinted from Johansson G, Andersson M and Akevaland HE (1984) *Journal of Chromatography* 298: 485–495. With permission from Elsevier Science.) (B) Distribution of protein and some glycolytic enzymes after CCD of an extract of bakers' yeast using 55 transfers. Without ligand-PEG (\times); with Procion Olive MX-3G PEG, 1% of total PEG (\square); and with Procion yellow HE-3G PEG, 1% of total PEG (\circ). System composition: 7% w/w dextran 500 and 5% w/w PEG 8000 including ligand-PEG, 50 mM sodium phosphate buffer pH 7.0, 0.2 mM EDTA, and 5 mM 2-mercaptoethanol. Temperature, 3°C. Systems in chamber 0–2 were initially loaded with yeast extract.

Figure 11 (A) Partitioning of Procion yellow HE-3G dextran 70 (PrY-Dx) depending on the degree of substitution, n (expressed in molecules of dye bound per molecule of dextran), in systems containing 50 mM sodium phosphate buffer (\blacktriangle); 10 mM sodium sulfate (\triangle); 100 mM sodium acetate (\square); 100 mM KCl and 5 mM sodium phosphate buffer (\bullet); or 100 mM $KClO_4$ (\circ), at pH 7.9. Arrow indicates K of unsubstituted dextran. System composition: 8% w/w dextran 70 and 4.5% w/w PEG 8000 including PrY-Dx (50 μM bound dye), and indicated salt. Temperature, 22°C and pH of system adjusted to 7.9. (Reprinted from Johansson G and Joelsson M (1987) *Journal of Chromatography* 411: 161–166. With permission from Elsevier Science.) (B) Effect of the concentration of PrY-Dx on the partitioning of the enzyme glucose-6-phosphate dehydrogenase (G6PDH) using PrY-Dx with n equal to 1.3, \square ; 2.3, \blacksquare ; 5.3, \bullet ; and 8.3, \circ . System as in (A) with 50 mM sodium phosphate buffer.

one or just a few dye ligands is shown in Figure 11. Since the dye ligands used here carries seven to ten charged groups per molecule they also add a considerable (negative) net charge to the ligand dextran. Its partitioning will then be sensitive to the presence of salt and the choice of salt. The ligand–dextran can be directed either to the bottom phase or the top phase. This steering is more effective the greater the number of ligands per dextran molecule.

The effect of ligand–dextran on the partitioning of an enzyme, glucose-6-phosphate dehydrogenase, is shown in Figure 11. There is also a tendency towards affinity precipitation when the concentration of ligand molecules is equal to the concentration of enzyme binding sites in the system. This is seen as a shallow dip in the extraction curve.

Use of a Third Polymer as Ligand Carrier

The ligand can be bound to a third polymer chosen in such a way that it will be mainly concentrated in one phase. Alternatively, if it is carrying enough charged groups, it may be steered to one phase by using salts. The efficiency, measured as $\Delta \log K / \log K_L$, equal to the apparent number of binding sites of the protein, has in several cases showed that the most effective polymer for carrying the ligand is neither of the two phase-forming polymers. The effect of a dye ligand, bound to various polymers, on the partitioning of lactate dehydrogenase in a dextran–PEG system is presented in Table 4.

Table 4 The effect of ligand carrier on its efficiency in producing affinity partitioning

Ligand carrying polymer	$\Delta \log K_{LDH}$	$\log K_{L-polymer}$	$n_{app} = \Delta \log K_{LDH} / \log K_{L-polymer}$
Ficoll	2.11	0.90	2.3
Hydroxypropylstarch	0.59	0.32	1.8
Poly(ethylene glycol)	2.23	1.50	1.5
Dextran (D.S. = 8.3)	2.31	1.60	1.4
Ethylhydroxyethyl cellulose	2.06	1.63	1.3

Lactate dehydrogenase (LDH) was partitioned in systems containing 7% (w/w) dextran 500, 5% w/w PEG 8000, 25 mM sodium phosphate buffer, pH 7.5, and Procion yellow HE-3G polymer of dye concentration of 42 μM . Temperature, 22°C. (Reprinted from Johansson and Joelsson M (1984) *Journal of Chromatography* 411: 161–166. With permission from Elsevier Science.)

Chiral Affinity Partitioning

For separation of low molecular weight substances into their enantiomeric forms a system may be used where one of the phases contains a high molecular weight substance which binds one of the enantiomers. Bovine serum albumin as well as cyclodextrin have been used for this purpose.

Analytical Uses

Besides the preparative use of aqueous two-phase systems, they have been applied to a number of analytical studies of the properties of biological macromolecules and particles. Some of these uses are binding studies, conformational changes, studies of antibodies, and homogeneity studies of protein, nucleic acids, membranes, organelles and cells.

Multiphase Systems

By using more than two polymers, multiphase systems can be obtained. In principle, the number of phases can be as many as the kinds of polymers used. A three-phase system of PEG, Ficoll, and dextran has been used with two ligands (in different phases) for directing the partitioning of blood serum proteins.

Semi-organic Systems

Part of the water in a two-phase system may be replaced by certain solvents. Often dextran cannot be used because of low solubility but it may be replaced by Ficoll. The log K of a protein may change drastically by introducing the organic solvent. Also the $\Delta \log K$ may in some cases be reduced while in other cases has been found to remain relatively unaffected.

Affinity Partitioning of Nucleic Acids and Bioparticles

Affinity partitioning in aqueous two-phase systems is not restricted to proteins, but has been also used for purification of DNA, using base-pair specific ligands, membrane fragments, and cells, such as erythrocytes. Some examples of such affinity extractions are found in Table 2.

Future Prospects

More specific ligands will certainly come into use for affinity partitioning and systems with much lar-

ger partition coefficients will be developed. This will allow not only specific extraction of biomaterials but also their many-fold concentration. Effective recycling processes of ligand-polymers will make it economically feasible to use affinity partitioning for extraction of enzymes on a technical scale. Successive extraction of several components from one and the same source by using a number of ligands in series extraction can be foreseen.

Conclusions

Affinity partitioning is a method of selective liquid-liquid extraction for purification and studies of proteins and other 'water stable' cell constituents. The scaling up of this process is uncomplicated and the recovery of ligand polymer reduces the cost.

Biochemical Engineering Aspects of Affinity Separations

H. A. Chase, University of Cambridge,
Cambridge, UK

Copyright © 2000 Academic Press

Introduction

Affinity separations are popular methods for the purification of biological molecules and other biological entities. They can readily be implemented on the laboratory scale but a number of additional factors have to be considered when these techniques are to be used for production purposes. Under these circumstances it is necessary to apply biochemical engineering principles to the design, scale-up and optimization of affinity separations. These topics are the subject of this article.

Selective interactions are exploited in affinity separations in order to achieve greater adsorbent selectivity for the desired molecule. Subtle differences in physical properties such as charge, size and hydrophobicity are often found to be insufficient for the required degree of purification in many separations of biological compounds. Many separations require the isolation of a minority component from a highly complex feedstock which may contain large amounts of similar compounds. As a consequence, it has been necessary to devise recovery flow sheets that consist of an extensive sequence of different steps – a sequence that may result in low overall yields and excessive costs. Hence affinity separations have been developed as alternatives to the more widely used separations based on ion exchange, hydrophobic interaction and size exclusion methods. Provided

a ligand can be obtained which is truly selective for the desired component, it is possible to recover that component from a complex feedstock to a high degree of purity and in high yield. Typically the ligand is used in heterogeneous phase separations in which it is immobilized on to the surfaces of a porous solid-phase matrix material and employed in chromatographic and other adsorption techniques. Other approaches including the use of affinity ligands in selective precipitation and in modifying the phase selectivities in aqueous two-phase separations (ATPS) have been reported, but are not considered further here.

A variety of ligands with a wide range of molecular complexities have been developed for use in affinity separations and these are reviewed extensively elsewhere in this work. In many examples, duplication of the selective interactions that occur during the normal function of biomolecules have been exploited during such affinity separations; the affinity ligand is frequently one of the components of a recognition interaction. Examples include the recognition between an enzyme and its inhibitor or co-factor, or the highly specific interaction between an antigen and an antibody raised against it. Biomimetic molecules have been developed to mimic the recognition sites of more complex molecules, either by exploiting fortuitous interactions shown by readily available compounds (e.g. textile dyes) or as a result of the identification of new compounds either by studying the detailed three-dimensional structure of the target, or by the techniques of combinatorial synthesis. Selective molecular recognition can also be achieved without mimicking any naturally occurring

biological interactions. A typical example would be in the use of immobilized metal ion affinity chromatography in the purification of proteins and peptides containing poly-histidyl sequences.

Although affinity separations are frequently considered to be highly selective, they are not always good at selecting between closely related variants of essentially the same compound, e.g. when changes have occurred that do not result in elimination of the molecular recognition of the ligand. For proteins, such changes include minor amino acid variations during synthesis, partial misfoldings, and the formation of dimers and higher oligomers. Under these circumstances, separations that exploit differences in the size or subtle differences in the surface characteristics of the molecules are called for; affinity interactions are not sufficient.

Affinity separations are mainly used in preparative techniques where the adsorbent is chosen to interact selectively with the desired product and hence to be used as a tool for its purification. An equivalent approach can be used in analytical techniques if the goal of the analysis is determination of the level of one or a group of closely related compounds. However, such an approach is comparatively rare as other, less selective, techniques when operated

in a manner suited to the resolution of multiple components are able to yield, simultaneously, quantitative information about a larger number of components, even though such separations would not have sufficient throughput for use for preparative purposes. The approach that is adopted in this contribution is to introduce the considerations that are needed when affinity separations are to be used for preparative purposes at scales greater than that encountered in the laboratory (Table 1). Traditionally the approach and input of biochemical engineering to the optimization of bioprocesses is not considered important or necessary at the laboratory scale, where equipment and consumable costs are modest, and considerations such as yields, throughputs and batch cycle times are less important. The latter considerations become of much greater importance as the scale is increased through pilot to production procedures. However, much of what will be said is also applicable to the optimization of laboratory-scale procedures. The scale-up and optimization of affinity separations are characterized by features many of which are also of prime importance in the scale-up of other chromatographic methods and these should be considered in addition to the approach adopted here.

Table 1 Biochemical engineering aspects of affinity separations

<i>Criterion</i>	<i>Pertinent aspects</i>	<i>Implications</i>
Choice of affinity ligand	Selectivity Strength of binding Chemical identity and origin	Purification achieved Elution conditions Adsorbent longevity Cost Regulatory implications
Choice of immobilization material	Surface area Mass transfer characteristics	Contactor configuration and volume Separation time
Position in process flow sheet	Reduction in overall number of steps Feedstock composition Feedstock volume	Process economics Adsorbent longevity CIP procedures Contactor design Bed volume Adsorbent kinetics
Process design	Optimization of separation performance Choice of liquid-phase compositions, flow rates and stage durations	Laboratory-scale process development Computer modelling
Scale-up	Preservation of separation performance	Design heuristics and computer modelling
Monitoring and control	Measurement of levels of target molecule Detection of fault conditions	Online process optimization Improved yield and productivity Manufacture to GMP standards
Process validation	Manufacture to GMP standards	Equipment installation and commissioning Process reproducibility and robustness
Economic	Minimization of costs Competitiveness with alternative separation procedures	Adsorbent choice and longevity Liquid-phase selection Waste minimization, disposal and recycling

Position in Process Flow Sheet – Direct Recovery

One of the most important initial decisions regarding the adoption of an affinity separation technique in a recovery flow sheet is the selection of the point when that step should occur. Considerations of the expense and fragility of affinity ligands have often resulted in affinity separations being reserved for the later stages of a separation procedure, where, in general, the feedstocks are cleaner and the volume of liquid to be processed is less. Under such circumstances, affinity adsorbents would be expected to be able to be used for more cycles of operation, and each cycle of operation could be conducted in a smaller bed. Both these features would reduce process costs. However, this conservatism often results in underutilization of the potential resolving power of the affinity separation technique. The possibility of using a highly selective adsorbent for the capture and purification of an adsorbate from a very crude feedstock logically dictates that such a technique should be used at a very early stage in a separation protocol, thus eliminating the need for a series of less selective separation steps, each involving additional expense and a reduction of overall yield. However, the early stages of a separation protocol often involve feedstocks that contain particulates, including whole cells, pieces of broken cells and subcellular structures. The application of such feedstocks directly to packed beds results in the clogging of the bed arising from the capture of the particulates within the bed voids. Such feedstocks are typically pre-clarified by centrifugation or microfiltration, i.e. the use of techniques that not only may have expensive capital and running costs, but also may result in significant reductions in product yields. Recent advances in biochemical engineering have led to the development of a new technique to overcome the need for pre-clarification of the feed before application to an adsorbent bed. Expanded bed adsorption involves the use of beds with greater void volumes created by fluidizing the adsorbent beads in a stable manner as a result of upwards flow of liquid through the bed. Affinity ligands have been used with success in expanded bed adsorption techniques in order to achieve capture, concentration, clarification and purification in a single stage process.

Choice of an Appropriate Affinity Ligand and Immobilization to a Support

There are a number of factors that have to be considered when choosing an appropriate affinity ligand for use in affinity separations. One critical

consideration is the selection of a ligand with appropriate affinity and selectivity towards the target molecule. Although the selection of ligands that form complexes with very low dissociation constants improves capture of adsorbate from feedstocks at low concentrations and permits extensive washing of the adsorbed complex to remove less tightly adsorbed impurities, it may prove difficult to achieve dissociation of the complex during the subsequent elution phase. Elution may need to be achieved as a result of major changes to the physical conditions of the irrigating buffer (e.g. pH, ionic strength) with the possibility of subsequent denaturation of the adsorbate and/or the ligand. In addition, there is the possibility that dissociation of the adsorbed complex will be slow as a result of low values of the rate constant of this step. When being used on a large scale, the cost of the affinity ligand and the number of cycles in which it can be used are also important considerations. Problems and costs associated with the manufacture of ligand in the quantities required to prepare large amounts of affinity adsorbents may become significant, together with any implications that the nature and the source of the ligand may have on the validation of the process. It may prove impossible to find ligand immobilization chemistries that totally prevent low levels of ligand leakage from the affinity adsorbent during all phases of the purification cycle. The use of affinity separations in the production of therapeutic products dictates the need for these processes to be operated in a manner that can be fully validated to comply with good manufacturing practice (GMP). The need for thorough sanitation as part of the inherent clean-in-place (CIP) procedures may necessitate exposure of the affinity ligand to harsh reagents or sterilization protocols not previously encountered during use of the technique in the laboratory, with a consequent increase in the likelihood of deterioration of the affinity adsorbent.

Once a suitable affinity ligand has been chosen, it has to be immobilized on to a suitable support in order to generate an affinity adsorbent. Considerations in the choice of a suitable support are common to those that would be used in other adsorption and chromatographic procedures. In general the use of porous particles has been the most popular in large-scale separations, although the benefits of using membrane materials in achieving fast mass transfer have been demonstrated in some small-scale systems. Important properties of a suitable support include:

- High surface area accessible by the target molecule per unit volume of matrix, to minimize the volume of the adsorbent needed for the separation.

- Spherical particle shape and narrow particle size distribution to facilitate packing the bed to obtain optimal flow characteristics.
- Good mechanical properties of the matrix to resist compression and compaction in tall beds operated at high flow rates at high pressure drops and to resist attrition should removal of the adsorbent from the bed be necessary periodically for thorough sanitation procedures.

A wide variety of matrices, designed specifically for use in process-scale separations, are commercially available. In some cases, they may be purchased with popular, widely used, affinity ligands already covalently immobilized on their surface. Alternatively, base matrices may be available in a chemical form which facilitates customized covalent immobilization of more specialized ligands.

Operating Protocols, Equipment, Monitoring and Control

Affinity separations are carried out using equipment that is suitable for use in other adsorption and chromatographic procedures. In almost all cases this will involve the use of a packed bed of adsorbent, although the benefits of using expanded bed adsorption technology when processing particulate-containing liquids are also rapidly becoming apparent. These affinity procedures are operated in a batch mode with a number of sequential stages during each cycle of operation (adsorption, washing, elution, cleaning, re-equilibration). Reasons for the choice of such methods include the ease of automation and improved quality assurance over stirred tank adsorption procedures. Valves can be employed to ensure that the appropriate process solutions (feedstocks, buffers, eluents, etc.) are pumped on to the bed and that liquid fractions from the bed are diverted to appropriate vessels for collection. Typically these actions are under the control of an automated system which either follows a pre-programmed time sequence, or responds interactively to the features of the separation by exploiting information being received from sensors and monitors installed in the process.

In order to run an affinity separation optimally, it is necessary to be able to monitor the success of the separation as it is proceeding. Ideally, information is required on the levels of key components that accurately reflect the state of the separation. In affinity separations such components will include the adsorbate itself, the level of total protein and possibly the levels of key contaminants. The on-going development of biosensors able to provide continuous

measurement of particular compounds will be of crucial importance in this area. Meanwhile, use is beginning to be made of techniques such as flow injection analysis, surface plasmon resonance sensors and rapid liquid chromatographic monitoring. These techniques yield much more specific information than is available from traditional flow measurement techniques such as spectroscopy (mainly used to measure the general level of protein) and pH and conductivity measurements whose contribution is restricted to monitoring the physical properties of the liquids flowing into and out of the column. The ability to be able to monitor online the levels of particular compounds enables optimization of the duration of the adsorption stage of the separation, terminating it when the level of the target compound begins to break through the bed without being captured. Such monitoring can also participate in the location of the target in the flow from the bed during elution.

Scale-up and Validation

One of the principal biochemical engineering considerations associated with affinity separations is to transform a successful laboratory separation procedure into a viable industrial unit operation. Packed bed separation procedures can be successfully scaled up to almost any extent provided certain rules are maintained and scale-up of affinity separations can also be achieved in a rational manner without difficulty. A suggested approach is:

- Ensure that the same adsorbent (including the chosen particle size) is used in both laboratory and large-scale procedures.
- Conduct investigations to determine the approximate dynamic capacity of the affinity adsorbent for the desired product and estimate the volume of the bed that will be needed to process the scaled-up batch size.
- Select a bed height of adsorbent that is compatible with the above volume. This will depend to a large extent on the diameters of commercially available columns, paying due regard to manufacturers' recommendations concerning minimum bed height to diameter ratios to achieve satisfactory flow distribution across the bed and maximum bed heights recommended to avoid excessive pressure drops and resultant bed compression.
- Optimize all stages of the separation in laboratory experiments using narrow columns of the same height as chosen for the full sized bed.
- Maintain the linear flow velocities and durations of each stage of the optimized laboratory process in the scaled-up procedure.

Adherence to these procedures should ensure that the characteristics of the separation and cycle time of the separation are maintained.

Before any downstream purification process can be used in the production of therapeutic agents it must be validated as part of the procedure to ensure compliance with GMP. For affinity separations, the issues are similar to those pertaining to any adsorption or chromatographic procedure. However, quality assurance issues associated with the source and origin of the affinity ligands may be of additional importance especially if these are molecules isolated from natural sources. Issues such as installation qualification and operational qualification and the associated documentation are dealt with in depth by Sofer and Hagel (see Further Reading).

Optimization

Two approaches to the optimization of affinity separations can be identified. The first 'practical' approach makes use of information and experience gained from experimentation, typically at the laboratory scale. Such an approach may be expensive and time consuming and may require the availability of substantial amounts of the target biomolecule, a situation that may be highly undesirable in the early stages of the development of a product with possible therapeutic value. The second 'theoretical modelling' approach is based on the philosophy that a complete understanding of the events that occur during an affinity separation can lead to optimization being achieved by computer-based methods. Such a situation is potentially cheaper and quicker, but requires confidence that the modelling approach adopted accurately describes the true situation. Sometimes it is necessary to combine the two approaches.

In addition to optimization of the choice of affinity ligand and the materials and methods for its immobilization, which have already been described above, a number of factors have to be considered when optimizing an affinity separation. These factors, which will have an influence on each other, include:

- Choice of flow rates. It is necessary to adopt a suitable compromise between fast rates to minimize purification time and slow rates to allow mass transfer and kinetic processes to occur. The nature of the matrix material chosen for the process and its resultant mass transfer characteristics strongly influence this consideration;
- Choice of irrigating liquid. The success of washing and elution procedures depends critically on the influence the liquid has on the strength of the

adsorbent/adsorbate complex, particularly in relation to its effect on complexes of other compounds adsorbed specifically or non-specifically.

- Cutting the eluted peak. Most affinity separations achieve resolution and purification in the adsorption stage resulting from the specificity of the affinity ligand. However the use of 'group-specific' ligands may result in the adsorption of compounds other than the desired target. Under these circumstances attempts may be made to resolve the adsorbed species by use of a series of step changes in eluent composition and/or the use of a continuous gradient, and it is necessary to identify the portion of eluent containing the target compound. The cut may be made as a compromise between the yield and the degree of purification required.

Theoretical Modelling

A number of approaches have been adopted for the modelling of adsorption and chromatography operations in computer-aided process engineering. Some of these describe the features of the separation in gross, overall terms and essentially describe the mass balance over the process. Alternatively, other attempts have involved a detailed consideration of the details of such processes. One approach towards understanding the features that dictate the success and characteristics of an affinity separation has involved a detailed study of the nature and characteristics of the equilibrium and mass transfer processes for the adsorption/desorption of the adsorbate, and in some cases other key components in the separation. The nature of adsorbents adopted for use in practical affinity separations results in a totally thorough approach to modelling being complicated and impractical. Accurate analysis is frustrated by the presence of a distribution of particle diameters and pore characteristics, in addition to a non-homogeneous distribution of immobilized ligand throughout the interstices of the adsorbent. It has often been necessary to use approximate methods that overlook the latter complications. In general, the modelling of preparative chromatography is also difficult as a result of the need to consider the simultaneous adsorption of multiple species. However, the fact that affinity separations often involve the adsorption of only one or a few components can simplify the task. It must be remembered that although the selection and subsequent solution of a set of algebraic equations which describe the characteristics of an adsorption system can often be undertaken, it is also essential to obtain values for the parameters used in such equations which apply to the actual separation under

Table 2 Strategies for optimizing the stages of affinity separations

Stage	Criteria of efficiency	Achieved by
Adsorption	Sharp breakthrough curves	Adsorbents with good kinetic properties (small particles, adsorption to outer surfaces) Low flow rates High inlet concentrations of adsorbate
Washing	Selectivity Maximum removal of contaminants, minimum removal of adsorbate	Appropriate choice of ligand Appropriate choice of buffers
Elution (gradient)	Maximum concentration of product	Reversed flow direction Strong eluents Low flow rates
Elution (step)	Minimum denaturation of product	Weak eluents High flow rates

consideration. Commercial packages are now available which are reported to be effective for scale-up and optimization of affinity separations, although substantial improvements to a process can also be made on the basis of a qualitative understanding of the basic features of an affinity separation (Table 2).

It has already been pointed out that resolution in affinity separations is almost always achieved during the adsorption process and is less likely to be necessary during elution unless the specificity of the affinity ligand is low and multiple species have been adsorbed. Hence the majority of effort has been expended towards understanding the events that occur during the adsorption stage of the separation and is thus directed towards optimizing the duration of the adsorption stage to ensure that the potential adsorption capacity of the bed is utilized as far as possible, i.e. full use has been made of the costly immobilized ligand. Of particular importance is the correct assessment of the amount of adsorbate that can be removed from the feedstock during a cycle of operation. This requires knowledge of not only the maximum capacity of the adsorbent (q_m) but also the dissociation constant (K_d) of the adsorbed species. It is important to remember that the capacity of the adsorbent is governed by the nature of the adsorption isotherm, even when kinetic limitations allow the adsorbent to become loaded to equilibrium with the feedstock. In many cases, the equilibrium characteristics have been shown to be adequately described by a simple Langmuir isotherm, although the situation is certainly more complicated where more than one component can bind to the adsorbent. The shape of the adsorption isotherm is in most cases hyperbolic, with characteristics described by:

$$q = \frac{q_m c_A}{K_d + c_A}$$

Only in situations where the concentration of adsorbate in the feedstock, c_A , is of greater magnitude than the value of the dissociation constant of the adsorbed species (K_d) will the affinity adsorbent show equilibrium binding capacities as great as the maximum adsorption capacity (q_m). Indeed for values of c_A smaller than K_d , the equilibrium capacity of the adsorbent (q) decreases linearly with decreasing c_A and is given by

$$q = \frac{q_m c_A}{K_d}$$

This simple consequence of the law of mass action often accounts for the apparently low adsorption capacities that are observed during the development of affinity separations which are frequently mistakenly identified as a malfunction of the adsorbent. This point shows the importance of knowing the value of K_d of the selected ligand, but also the need to select an affinity ligand where the dissociation constant of the adsorbed complex with adsorbate is sufficiently low to ensure satisfactory capture of adsorbate from feedstock, particularly if attempts are being made to capture an adsorbate present at low concentrations.

Economic Considerations

Evaluation of the economics of the separation requires consideration of the fixed costs of the equipment (columns, reservoirs, pumps, valves, monitors, control system), and the running costs including the cost of the adsorbent, the chemicals used (including the need for large volumes of high quality water) and labour charges.

Although much attention is appropriately paid to the cost and longevity of the affinity adsorbent and its attached ligands, concentrating particularly on the number of cycles in which the adsorbent can be

used, due consideration must also be paid to the costs of all stages of the separation procedure. Such consideration should cover not only the basic costs of the chemicals employed, but also all costs associated with disposal and/or recycling of those chemicals after use. Some affinity procedures may involve specific eluents (e.g. enzyme co-factors) whose expense is greater than that of the simple strategies of changes in pH, ionic strength or dielectric constant used to elute many adsorbates. These economic considerations become of much greater importance in the design of process-scale procedures and are often overlooked at the laboratory scale.

Conclusions and Future Prospects

There are no technical barriers preventing the use of affinity separations in the production of biological molecules and entities. The biochemical engineering principles associated with the scale-up and optimization of affinity separations are well developed and the resultant conclusions are readily implemented. The conservatism surrounding their current use stems from the widespread lack of suitable affinity ligands. It is anticipated that novel molecules emerging from new techniques such as phage display technology and combinatorial chemistry will be excellent candidates for use of ligands in affinity separations. Affinity separations will be used in the purification of soluble biomolecules and also in the isolation of more complex species such as viruses, cells and other products for use in gene therapy. Affinity separations will therefore play an essential part in the preparation of future generations of therapeutic biotechnological products. Their adoption will result in the simplification and improvement of downstream processing flow sheets and will enable a rapid transition between discovery and utilization of these products.

Covalent Chromatography

K. Brocklehurst, University of London, London, UK

Copyright © 2000 Academic Press

Introduction

Conventional affinity chromatography involves specific recognition of biomolecules such as antibodies and enzymes by immobilized ligands (antigens and

inhibitors) usually by a multiplicity of non-covalent interactions. By contrast, the separation process in covalent chromatography does not require specific adsorptive binding and thus does not require knowledge of the structural determinants of the binding area of the component to be isolated. Instead, specificity relies on the nature of the chemical reaction of the chromatographic material with one or more components of a mixture. When complete specificity is

achieved in the bonding step, only one of the components reacts. The other components are removed by washing and the bonded component is then released by another chemical reaction. Ideally this leaves the chromatographic material in a form that is readily regenerated. When several components react with the chromatographic material, specific isolation of individual components needs to be achieved subsequently, e.g. in the elution step (sequential elution covalent chromatography). A recent extension of covalent chromatography involves derivatization specifically of thiol-containing components by reaction

with a dithiopyridyl polyethyleneglycol (PEG) reagent. This provides charge shielding effects and facilitates separation of the derivatized proteins by ion exchange chromatography.

The development of covalent chromatography is discussed below and is summarized in **Table 1** in which key papers and reviews are identified. Those key papers not listed in the Further Reading section may be found in one or more of the reviews. Widespread application of the technique began after 1973, when covalent chromatography by thiol–disulfide interchange using the 2-mercaptopyridine leaving

Table 1 Milestones in the development of covalent chromatography and some key publications

1963	<i>Fundamental paper</i> reports the synthesis of an 'organomercurial polysaccharide' for the isolation of thiol-containing proteins and the first example of covalent chromatography (Eldjarn and Jellum).
1970	<i>Fundamental paper</i> reports unusual high reactivity of the thiol group of papain towards 2,2'-dipyridyl disulfide (2-Py-S-S-2-Py; 2PDS) at pH 4 which provided the basis for covalent chromatography by thiol–disulfide interchange with provision for selectivity for low pK_a thiol groups (Brocklehurst and Little).
1972	<i>Fundamental paper</i> reports an early example of covalent affinity chromatography (a combination of covalent and conventional affinity chromatographies) in which penicillin-binding proteins are isolated by reaction with the β -lactam ring of immobilized 6-aminopenicillamic acid and released by reaction with hydroxylamine (Blumberg and Strominger).
1973	<i>Fundamental paper</i> introduces covalent chromatography by thiol–disulfide interchange for the isolation of fully active papain using a Sepharose-(glutathione-2-pyridyl disulfide) gel (Brocklehurst, Carlsson, Kierstan and Crook; marketed by Pharmacia).
1975	<i>Fundamental paper</i> reports the synthesis and use of a more highly substituted gel with an electrically neutral and less sterically demanding spacer, the Sepharose 2-hydroxypropyl-2'-pyridyl disulfide gel (Axén, Drevin and Carlsson; marketed by Pharmacia).
1978	<i>Fundamental paper</i> reports the introduction of <i>N</i> -succinimidyl-3-(2'-pyridyl disulfany)l propanoate which readily permits the introduction of auxiliary thiol groups into non-thiol-containing proteins to widen the scope of targets for reversible immobilization by thiol–disulfide interchange (Carlsson, Drevin and Axén).
1980	<i>Review</i> cites approx. 150 papers on covalent chromatography published between 1973 and 1978; although most publications are concerned with thiol-containing proteins, there are some references to covalent chromatography involving serine, methionine and tryptophan side chains and to the isolation of nucleic acids and membrane fragments (Lozinskii and Rogozhin).
1981	<i>Fundamental paper</i> reports development of sequential elution covalent chromatography to separate protein disulfide isomerase and glutathione insulin transhydrogenase (Hillson).
1982	<i>Review</i> discusses selectivity by proton-activated covalent chromatography using 2-pyridyl disulfide gels in acidic media as a logical extension of the more general use of soluble disulfides containing the 2-mercaptopyridine leaving group in protein chemistry and enzymology as enzyme active centre titrants, reactivity probes, delivery vehicles for spectroscopic reporter groups and heterobifunctional crosslinking reagents (Brocklehurst).
1983	<i>Fundamental paper</i> reports the use of (Gly-Phe-Phe) ₂ -cystamine immobilized on Affi-Gel10 (BioRad) for the isolation of cathepsin B; this is an example of an extension of the general method of covalent chromatography by thiol–disulfide interchange by provision of recognition sites to create a covalent affinity gel (Evans and Shaw).
1985	<i>Review</i> discusses covalent chromatography and its applications in biochemistry and biotechnology; extensive detailed descriptions are given of the synthesis, characteristics and commercial sources of activated support materials (Brocklehurst, Carlsson and Kierstan).
1995	<i>Fundamental paper</i> reports examples of selectivity in covalent chromatography by thiol–disulfide interchange determined by steric and electrostatic restrictions (Thomas, Verma, Boyd and Brocklehurst).
1996	<i>Review</i> summarizes applications of covalent chromatography by thiol–disulfide interchange with references also to the use of some other types of thiol-specific chromatography: organomercurials, isothiocyanates and 4-aminophenylarsenoxide-agarose for the selective isolation of molecules containing vicinal thiol groups (Brocklehurst).
1996	<i>Fundamental paper</i> discusses an example of a development of covalent chromatography whereby monomethoxypolyoxy-(ethylene glycol) (mPEG)-(glutaryl)-S-S-2-Py is used to derivatize components of a mixture of thiol-containing enzymes to facilitate their separation by ion exchange chromatography (Azarkan, Maes, Bouckaert, Thi, Wyns and Looze).

Table 2 Applications of covalent chromatography by thiol–disulfide interchange using 2-pyridyl disulfide-containing gels or 2-pyridyl disulfide derivatives of the target protein or peptide

Applications	Comments
Fractionation and specific isolation of thiol-containing proteins and peptides	Purification of a wide range of enzymes and other proteins by the various versions of the technique has been reported
Isolation and sequencing of thiol-containing peptides	Facilitates purification of thiol-containing peptides which is often difficult from proteolytic digests. Two versions: (i) immobilization of the protein by reaction with the disulfide gel followed by proteolysis; (ii) derivatization of the protein by reaction with 2PDS, proteolysis in solution and isolation by reaction with the thiolate gel
Removal of prematurely terminated peptides during solid-phase peptide synthesis	Premature chain termination of the peptide by blocking of the free terminal amino group results in unwanted by-products in solid-phase peptide synthesis. These are readily separated from non-terminated peptides by addition of Cys-Met to the free amino group of the non-terminated peptide prior to cleavage from the solid-phase matrix in preparation for covalent chromatography
Reversible immobilization of enzymes with associated purification	This method contrasts with most methods of immobilization which are irreversible. An additional advantage is that eventual release of the enzyme by thiolysis can produce purified enzyme if the preparation applied was not fully active
Synthesis of specific adsorbents for conventional affinity chromatography	Thiol–disulfide interchange provides a convenient method of attaching ligands containing specific recognition features to insoluble matrices

group was introduced by Brocklehurst *et al.*, initially for the specific isolation of the fully active form of the cysteine proteinase, papain.

Various approaches developed subsequently are discussed including the range of gel types, the reactions involved in attachment, elution and gel reactivation and brief discussion of specific covalent attachment via groups other than thiol groups. The range of applications of covalent chromatography by thiol–disulfide interchange is summarized in Table 2.

Development of the Technique

Scope

Most of the published papers on covalent chromatography relate to proteins and peptides. The emphasis has been on thiol-containing molecules but immobilization procedures via the side chains of serine, methionine and tryptophan have been devised. In addition the use of covalent chromatography for the isolation of polynucleotides, low M_r co-factors, and gene fragments has been reported.

The Pre-Pyridyl Disulfide Era

The first example of covalent chromatography dates from 1963 when Eldjarn and Jellum reported the use of an organomercurial dextran based on Sephadex G-25 (Figure 1A) for the isolation of thiol-containing proteins which are released from the gel by treatment

with low M_r mercaptans. Simpler and more effective products using a better support material (agarose) were developed subsequently, e.g. by Cuatrecasas

**Figure 1** Some organomercurial gels. (A) Due to Eldjarn and Jellum, 1963. (B) Due to Cuatrecasas, 1970. (C) Due to Sluyterman and Wijdenes, 1970.

(Figure 1B) and by Sluyterman and Wijdenes (Figure 1C) both in 1970. Some solid phase organomercurials are available commercially but as Lozinskii and Rogozhin pointed out in their review in 1980 (Table 1) relatively little interest was shown in the technique of covalent chromatography until the introduction of the version involving thiol–disulfide interchange using a solid phase 2-pyridyl disulfide gel in 1973 (Table 1). Problems with organomercurial gels include gradual loss of the metal with consequent contamination of the purified protein, lack of absolute specificity for thiol groups and lack of provision both for designed selectivity and of a means of spectral monitoring of occupancy of gel sites by the target protein.

Covalent Chromatography by Thiol–Disulfide Interchange Using 2-Pyridyl Disulfide Gels

The reactions involved in attachment, elution and gel reactivation Covalent chromatography using insoluble mixed disulfides containing the 2-mercaptopyridine leaving group (Gel-spacer-S-S-2-Py) was devised by Brocklehurst *et al.* in 1973 as a logical extension to the use of 2,2'-dipyridyl disulfide (2PDS or 2-Py-S-S-2-Py) as a thiol titrant with selectivity in acidic media for intact catalytic sites in the cysteine proteinase papain. In 1970 Brocklehurst and Little had observed unusually high reactivity of the thiol group of Cys25 in papain towards 2PDS which has its origin in the coexistence of the catalytic site ion pair motif, (Cys25)-S⁻/(His159)-Im⁺H, and the activated, protonated form of the disulfide, 2-Py-S-S-2-Py⁺H. The coexistence of significant concentrations of these reactants arises from the low pK_a value for ion pair formation (3.3) and its relationship to the pK_a value of the 2-Py-S-S-2-Py⁺H cation (2.45). Soluble reagents of the general type R-S-S-2-Py (reviewed by Brocklehurst in 1982; see Table 1) have proved useful in the study of thiol-containing proteins, e.g. as enzyme active centre titrants, reactivity probes, delivery vehicles for spectroscopic reporter groups and crosslinking reagents. 2,2'-Dipyridyl disulfide and simple alkyl-2-pyridyl disulfides successfully titrate intact catalytic sites in cysteine proteinases even in the presence of low M_r mercaptans or denatured enzyme that still retains its thiol group but with the ion pair disrupted. It was as part of a programme designed to exploit the two-protonic-state nature of reagents of the type R-S-S-2-Py⁺H/R-S-S-2-Py where the protonated forms possess reactivities *c.* × 1000 greater than those of the unprotonated forms that covalent chromatography was originally devised. Thus selectivity of attachment in favour of low pK_a thiol groups may be achieved by carrying out

the attachment procedure at pH *c.* 4 where reaction is with the protonated gel (Gel-spacer-S-S-2-Py⁺H (see Figure 2A) and reaction of thiol groups with 'normal' pK_a values (8–10) will not occur because these will exist in the non-nucleophilic RSH forms. The technique is more generally applied in weakly alkaline media (pH 8) where reaction with the unprotonated gel (Gel-spacer-S-S-2-Py) (see Figure 2B) would be expected to occur readily with most thiol-containing compounds. Thus when covalent chromatography using a Sepharose-spacer-2-pyridyl disulfide gel is applied to the isolation of thiol-enzymes at pH 8, thiol-containing protein is freed from irreversibly oxidized and hence inactivated enzyme containing sulfinic acid (–SO₂H) groups in place of thiol groups. When applied, e.g. to cysteine proteinases at pH 4, attachment is specifically by reaction of the catalytically active form of the enzyme containing the essential (Cys)-S⁻/(His)-Im⁺H ion pair generated by protonic dissociation with pK_a of about 3.

Reaction of the thiol-containing protein with either protonation state of the gel may be quantified by spectral analysis of the chromophoric pyridine-2-thione released in the thiol–disulfide interchange (λ_{max} 343 nm, $\epsilon_{343} = 8080 \text{ M}^{-1} \text{ cm}^{-1}$). This provides a measure of the practical capacity of the gel for a particular protein. The theoretical capacity may be determined by reaction of the 2-pyridyl disulfide sites in the gel with a low molecular weight mercaptan such as 2-mercaptoethanol and spectral analysis of the pyridine-2-thione released into solution. The practical capacity is usually less than the theoretical capacity due to the inaccessibility of some sites to macromolecules. After removal of unreactive components by washing, the thiol-containing protein is released from the gel by elution with a reducing agent, usually a low molecular weight mercaptan (Figure 2C). During elution the gel is left in the non-activated, thiolated state (Gel-spacer-SH) and may be reactivated by reaction with 2PDS (Figure 2D).

An alternative version of this type of covalent chromatography involves derivatization of the thiol-containing protein (PSH) by reaction with 2PDS and attachment by reaction of P-S-S-2-Py so produced to a non-activated thiolated gel (Figure 2E). Other disulfide gels have been used subsequently for covalent chromatography, such as those prepared by reaction of thiol groups in gels with 5,5'-dithiobis-(2-nitrobenzoate). Such gels lack the ability to increase their reactivity by protonation at low pH and thus do not offer the possibility of selectivity that 2-pyridyl disulfide gels provide.

Support materials and spacers As in other separation techniques the solid support for the reactive

groups in covalent chromatography must have sufficient mechanical, chemical and biological stability to resist degradation during the chromatographic process. It needs to be sufficiently permeable to permit access of macromolecules to reactive groups within the support material and sufficiently inert so as not to denature the molecules to be isolated. Spherical beads provide good column packing and flow properties. The support must allow opportunities to introduce the chemically reactive groups required for the immobilization process without serious perturbation of the other properties mentioned above. The support that has been most widely used in covalent chromatography is the polysaccharide, agarose. Beaded agarose is available, e.g. as Sepharose 2B, 4B and 6B and as crosslinked products with increased mechanical stability such as the CL-Sepharoses. The original (1973) version of covalent chromatography by thiol-disulfide interchange utilized the gel shown in **Figure 3A**, prepared by reaction of cyanogen-bromide-activated agarose with the amino group of glutathione followed by reaction of the thiol group with 2PDS. Use of the 5-nitro derivative of 2PDS provides an activated gel that releases a coloured thione (λ_{max} 386 nm) during the attachment of a thiol-protein. Spacers other than glutathione (e.g. cysteine, cysteamine and ethane) have been attached to agarose but the activated gel shown in **Figure 3B**, reported in 1975 by Axén *et al.* (**Table 1**) is particularly noteworthy. Whereas the glutathione gel (**Figure 3A**) is negatively charged, the hydroxypropyl gel (**Figure 3B**) is electrically neutral and, in addition, is more highly substituted and less sterically demanding. The difference in these characteristics accounts for the different selectivities exhibited by the two gels demonstrated in 1995 by Thomas *et al.* in connection with studies on the highly negatively charged enzyme actinidin and on chymopapain M, an enzyme that rejects all but the smallest ligands in one of its recognition sites. The activated glutathione gel bonds to all of the cysteine proteinases in *Carica papaya* except chymopapain M (for steric reasons) and fails to bond with actinidin because of electrostatic repulsions. More generally, the spacer between the gel and the reactive attachment site should not be long and hydrophobic in order to minimize non-specific hydrophobic effects. Neither should it possess substantial ion exchange properties. These requirements of course are common to any separation technique that relies on specific reaction or interaction with particular sites engineered into the gel. Other support materials that fulfil some or all of the requirements for a satisfactory chromatographic material include crosslinked polyacrylamide and inorganic materials such as porous

glass coated with hydrophilic polymers. An example of an inorganic material that has been used in covalent chromatography is the macroporous silicon oxide derivative (Figure 3C) reported by Lozinskii *et al.* in 1979.

Sequential elution covalent chromatography This extension to the technique was introduced by Hillson in 1981. A mixture containing different thiol-containing proteins is applied to a 2-pyridyl disulfide gel and in most cases all would be expected to react. Separation is achieved in this case in the elution step. Elution either with different concentrations of a given mercaptan or with a series of mercaptans each of different redox potential results in the

sequential elution of each component with consequent separation.

Use of mPEG–Enzyme Mixed Disulfides in Conjunction with Ion Exchange Chromatography

During the mid-1990s Looze and co-workers introduced the use of soluble mixed disulfides containing the usual 2-mercaptopyridine leaving group and derivatives of monomethoxypolyethylene glycol (mPEG; nominal molecular mass 5 kDa) (Figures 3D and 3E) for the isolation of thiol-containing enzymes by ion exchange chromatography. The chromatographic behaviour of the enzymes appears to be modified by the charge shielding effects of the PEG chain. This approach provides another means of separating components of mixtures of thiol-enzymes as an alternative to sequential elution covalent chromatography.

Other Types of Covalent Chromatography

Attachment via thiol groups Substitution of the 2-mercaptopyridine leaving group by other aromatic mercapto groups results in the loss of selectivity at low pH and does not appear to offer substantive advantage. The intramolecular agarose thiolsulfonates introduced by Carlsson and his colleagues in the mid-1990s provide an alternative to the mixed agarose–aromatic disulfide gels discussed above. Thiolated agarose is subjected to mild oxidation by potassium ferricyanide to produce disulfide groups followed by further oxidation to thiolsulfonate groups by a stoichiometric amount of magnesium monoperoxyphthalate. These gels also lack the opportunity to provide selectivity for low pK_a thiol groups at low pH. They do not require external leaving groups but because of that do not offer the possibility of measurement of reactive site content by thiolysis and spectral analysis. An example of covalent affinity chromatography using a substrate-like symmetrical disulfide (Gly-Phe-Phe)₂-cystamine immobilized by amide bond formation on Affi-Gel 10 was reported by Evans and Shaw in 1983. In this type of approach specific binding interactions align the nucleophilic (thiolate) and electrophilic (disulfide) reactants for the covalent bonding process.

In some applications thiol groups exist as part of the support material and one example involving reaction of thiol-agarose gels with thiol-proteins derivatized as mixed disulfides by reaction with 2PDS (Figure 2E) constitutes one of the alternative versions of covalent chromatography by thiol-disulfide interchange. A different application of thiol-agarose gels is in studies on nucleic acids. Cytosine and uracil residues in polynucleotides can be mercurated

without appreciable change in function. These derivatives form mercaptides by reaction with thiol-agarose and are eluted subsequently by treatment with a low molecular weight mercaptan.

Attachment by reaction of thiol groups is not restricted to reaction at electrophilic sulfur. The higher reactivity of arylisothiocyanates towards thiol groups than towards amines permits their use in thiol-selective covalent chromatography. An immobilized trivalent organoarsenical, 4-aminophenylarsenoxide-agarose, has been used for the selective isolation of molecules and assemblies containing vicinal thiol groups (lipoic acid and the 2-oxoglutarate dehydrogenase multienzyme complex of which lipoic acid is a covalently bonded co-factor). Attachment involves cyclic dithioarsenite formation. Elution by 2,3-dimercaptopropane-1-sulfonic acid releases the reduced (dimercaptan) form of lipoic acid.

Attachment via seryl hydroxy groups Organophosphate agarose derivatives are an obvious choice for isolation of proteins with highly reactive seryl hydroxy groups such as the serine hydrolases. Coupling of 2-aminoethyl 4-nitrophenyl methyl phosphonate to succinylated aminoagarose produced a material that reacted specifically with serine hydrolases such as acetylcholine esterase and chymotrypsin. The problem with these gels is the very slow release of the enzymes even by good nucleophiles that provide reactivation in analogous soluble systems.

Attachment via methionyl thioether groups The known selectivity of alkylating agents for methionyl residues in acidic media to produce sulfonium derivatives and the possibility of regeneration by sulfur nucleophiles led Schechter *et al.* in 1977 to produce a chloroacetamidoethyl polyacrylamide derivative for the isolation of proteins via methionyl side chains. The relatively severe conditions required for attachment (low pH and long reaction times) limit the applications of this method. The methionyl residue cannot be at the C-terminus because such residues are converted to homoserine residues and attachment is not achieved. Regeneration of the covalent chromatography material is not provided for in this method.

Attachment via tryptophanyl side chains Arylsulfonyl chlorides and sulfur monochloride (S_2Cl_2) selectively modify tryptophan residues in acidic media to form 2-arylsulfonyl tryptophan and 2-mercaptotryptophan moieties respectively. Rubinstein *et al.* used this knowledge in 1976 to prepare polyacrylamide derivatives that react covalently with tryptophan-containing peptides which are released in modified

forms by treatment with a low molecular weight mercaptan. The tryptophan side chain is converted to a 2-mercaptotryptophan side chain in the process. The method could find application in protein sequencing but is of limited use for protein isolation not only because of the necessary introduction of the mercapto group but also because of the requirement for acid stability of the protein.

Applications of Covalent Chromatography

The range of applications of covalent chromatography is illustrated in Table 2 by reference to methods that utilize thiol-disulfide interchange. Examples of these applications can be found in one or more of the reviews listed in the Further Reading section.

Concluding Comments

The ease with which specificity and selectivity can be provided in covalent chromatography involving attachment via thiol groups, together with the advantages due to the mild conditions required for attachment, elution and reactivation of the gel, account for the outstanding success of versions of the technique involving thiol-disulfide interchange, particularly those using 2-pyridyl disulfide sites. Attachments via other protein side chains are generally less satisfactory in these respects and have been used only to a limited extent. Often covalent chromatography has been used at a relatively late stage in the purification process but the successful isolation of bovine mercaptalbumin from crude extracts reported by Carlsson and Svenson in 1974 suggests that this approach should be considered in other cases. Some of the applications listed in Table 2 can be applied to non-thiol-containing proteins by the introduction of an auxiliary thiol group, e.g. by use of the valuable heterobifunctional reagent, *N*-succinimidyl-3-(2'-pyridyl disulfanyl) propanoate, introduced by Carlsson, Drevin and Axén in 1978 or by site-directed mutagenesis.

Dye Ligands

Y. D. Clonis, Laboratory Enzyme Technology,

Introduction

Dyes employed in protein and enzyme purification are synthetic hydrophilic molecules bearing a reactive, usually a chlorotriazine, moiety by which they can easily be attached to various polymeric supports. Among the various known reactive dye ligands, Cibacron Blue 3GA or F3GA (CB3GA, **Figure 1A**), an *ortho*-isomer of CI Reactive Blue 2, has attracted most attention from biotechnologists in protein purification. The foundations of the important role of CB3GA may well be attributed to pure historical accident; an anomalous gel permeation chromatography run of pyruvate kinase when using blue dextran as a void volume marker. It was later found that the blue chromophore, CB3GA, was responsible for binding the enzyme thus leading to co-elution of enzyme and blue dextran. As with many critical but unexpected discoveries, the importance and breadth of applications were hardly appreciated in those early days. Since then, CB3GA and other triazinyl dyes have been immobilized on to various supports and used in the affinity purification of many proteins and enzymes.

Development of Dye Ligands and Dye Affinity Adsorbents

The originally exploited dyes were commercial textile chlorotriazine aromatic polysulfonated molecules

which when attached to appropriate supports, usually bearing hydroxyl groups, yield dye affinity adsorbents. The range of shades of commercial dyes derives primarily from anthraquinone, azo and phthalocyanine chromophores bonded to suitable reactive functions such as triazinyl and other mainly polyhalogenated heterocyclics. Anthraquinone dyes produce blue and the phthalocyanines turquoise shades. Green dyes contain mixed anthraquinone–stilbene, anthraquinone–azo or phthalocyanine–azo structures, whereas most other shades are derived from the azo class.

Unlike most biological affinity adsorbents, the stability of dye affinity adsorbents is usually limited only by the support itself. Dyes offer clear advantages over biological ligands, in terms of economy, ease of immobilization, safety, stability and adsorbent capacity. The main drawback of textile dyes is their moderate selectivity during the protein-binding process. In spite of this, the overall size, shape and distribution of ionic and hydrophobic groups enable dyes to interact with the binding sites(s) of proteins sometimes fairly specifically, as for example, with the nucleotide-binding site of several dehydrogenases, kinases, and several nucleotide-recognizing enzymes. The dye–protein interaction should not be compared to a simple ion exchange type since binding is frequently possible at pHs greater than the *pI* of the targeted protein. Furthermore, dissociation of the dye–protein complex is often achieved specifically by competing ligands, suggesting interaction with the protein at discrete sites. The view is supported by chromatographic, kinetic, inactivation, affinity labelling and spectra difference studies.

The last few years have seen a novel approach for tackling the problem of dye selectivity, signalling the

Figure 1 Structures of the parent textile dye Cibacron Blue 3GA (CB3GA), (A) the three blue (B)–(D) and one yellow (E) biomimetic dyes, and the blue dye (F) for selective LDH precipitation.

beginning of a new era in affinity bioseparation. This approach is based on a generation of the so-called biomimetic dyes. By employing molecular modelling techniques, it is possible to redesign the parent dye (e.g. CB3GA) or design *de novo* a new dye in such a way that the resulting biomimetic dye mimics naturally occurring biological ligands, thus displaying increased selectivity for the targeted enzyme. Figure 1 shows the structures of the parent dye CB3GA (A) and four biomimetic dyes (B–E). For the case of the NAD^+ -dependent enzyme alcohol dehydrogenase (ADH), having used molecular modelling to compare the conformations that NAD^+ and CB3GA adopt during binding to the enzyme, it was possible to propose the biomimetic structure of Figure 1(B) that exhibits increased affinity for ADH as compared to CB3GA. Recently a family of anthraquinone biomimetic dyes has been designed specifically for (keto)carboxyl-group-recognizing enzymes. Each member of this dye family is composed of two enzyme-recognition moieties (e.g. Figure 1C). The terminal biomimetic moiety bears a (keto)carboxyl structure linked to the triazine ring, thus mimicking substrates of the targeted enzyme, e.g. L-malate dehydrogenase (MDH). The chromophore anthraquinone moiety remains unchanged and the same as that of the parent dye (Figure 1A), recognizing the nucleotide-binding site of MDH. Members of this dye family show increased affinity for the targeted enzymes and have been designed for other enzymes as well, e.g. L-lactate dehydrogenase (LDH). In the case of the orthophosphate ester hydrolase alkaline phosphatase, a biomimetic dye was designed by substituting the terminal 2-aminobenzene sulfonate of CB3GA for a 4-aminobenzene phosphonate ring (Figure 1D). The corresponding dye adsorbent offers an impressive purification of calf intestinal alkaline phosphatase of over 300-fold in a single chromatography step. The biomimetic structure of Figure 1(E) is a benzamidino-cationic yellow dye designed for a different application. The cationic dye bears a guanidino group, the same as the potent trypsin inhibitor benzamidine. When the dye is immobilized, it is able to separate the two main proteolytic constituents of crude pancreatic extract, trypsin and chymotrypsin, since only the former enzyme is adsorbed. The use of biomimetic dyes is expected to increase and help towards simplifying enzyme purification problems.

Development of the Techniques

Dyes, whether conventional or biomimetic, have been exploited by different affinity bioseparation

techniques for protein and enzyme purification, as described below.

Affinity Chromatography

Reactive chlorotriazinyl dyes are easily and safely immobilized on agarose and other polyhydroxylic supports (e.g. cellulose, polyacrylates) or, less often, on amino-group-bearing supports, after nucleophilic substitution in alkaline environment. Alternatively, a diaminoalkane (e.g. 1,6-diaminohexane) spacer molecule can be chemically attached to the chlorotriazine ring of the dye, before the resulting conjugate is immobilized on various pre-activated polyhydroxylic supports. Although chemical immobilization of reactive dyes on polyhydroxylic supports is the most straightforward and widely used technique, perhaps the most unusual one is immobilization via adsorption. For example, it is possible, first, to chemically attach to the reactive dye a hydrophobic 1H,1H-pentadecafluorooctylamine tail by nucleophilic substitution. Then, the dye–tail conjugate can be physically adsorbed on to hydrophobic fluorocarbon particles. Hydrophobic fluorocarbon supports can be transformed into surface-hydrophilic materials. In this case, hydrophobic perfluorocarbon tails are chemically attached to hydrophilic polyvinylalcohol (PVA). Afterwards, the PVA–tail conjugate is physically adsorbed on to the hydrophobic surface of Teflon® particles. Therefore, the transformed Teflon® surface is hydrophilic and rich in hydroxyl groups through which reactive dyes can be immobilized.

At the end of the immobilization reaction, the coloured adsorbent is washed to remove free dye, packed in a chromatography column, and equilibrated with the appropriate buffer for protein purification. The sample is applied and nonadsorbed proteins are washed off, before the desired protein is desorbed (eluted) by changing the composition of the buffer eluent. This is realized either by non-specific desorption techniques (i.e. change of the ionic strength or pH) or by specific desorption techniques, for example, introducing competing substances (i.e. substrates, inhibitors, metal chelators) in order to selectively perturb the enzyme–dye complex on the column.

In the development of a protein purification protocol, some form of adsorbent screening exercise should be performed as the first step. The adsorbent exhibiting the highest purification factor and recovery for the targeted protein on the one hand, and on the other hand the adsorbent showing no adsorption of the protein of interest but good total protein adsorption, are promising candidates for employment in

positive and negative affinity chromatography, respectively.

Although beaded porous polyhydroxylic supports have been used for decades in biochromatography, rapid mass transfer has only been achieved recently thanks to two novel chromatography supports. The 'flow-through particles', which are exploited in perfusion chromatography, have pores wide enough (0.6–0.8 μm) to allow convective flow through them. Smaller diffusive pores along the throughpore channels of these particles provide a high adsorption area with diffusion path lengths less than 1 μm . These particles reduce process time by improving mass transfer. An alternative for the same purpose is offered by hyperdiffusion chromatography; this uses rigid particles with their entire pore volume filled by a homogeneous flexible soft hydrogel where the affinity ligands are immobilized. The proteins can diffuse freely through the hydrogel network and interact with the ligand.

High Performance Affinity Chromatography

When the support is made of noncompressible, spherical particles of small diameter (e.g. 5–20 μm) and narrow size distribution (e.g. 0.2–2.0 μm) the technique is termed high performance affinity chromatography (HPAC). Silica-based supports have been used with dyes for HPAC, although silica has serious drawbacks: poor chemical stability in an alkaline environment; the need for derivatization with organofunctional silanes prior to dye immobilization; and relatively small pore size. In spite of its problems, silica is still used in HPAC mainly on an analytical scale. Synthetic high performance polyhydroxylic particles probably offer a better alternative to silica for HPAC. The chemistry of support activation and dye immobilization is generally the same as that for softer materials, as described earlier.

A different concept for column packings was introduced by the following two materials: deformed nonporous high performance agarose; and nonporous fibres. The former support consists of 12–15 μm diameter nonporous beads which, when compressed, are claimed to result in superior resolution at high flow rates. The latter support consists of nonporous fibre-form quartz material of mean diameter 0.5 μm . This material has first to be silylated prior to proceeding with ligand immobilization. The above materials are potentially suitable for use with dye ligands.

Centrifugal Affinity Chromatography

Centrifugal affinity chromatography combines the high flow rate, created by centrifugation force, with the specificity of affinity chromatography. It

is an alternative to closed column chromatography (i.e. columns with adapters at their ends minimizing dead volumes) which usually but not always requires elaborate instrumentation. This technique has demonstrated its usefulness in the removal of albumin from human serum using immobilized CB3GA, and in the rapid screening of a large number of immobilized dyes for binding goat IgG.

Heterobifunctional Ligand Affinity Chromatography

The principle of heterobifunctional affinity ligand chromatography requires that a soluble heterobifunctional affinity ligand possessing two different affinity moieties is available. This alone may be a drawback for the technique, when considering factors such as labour and cost. One moiety is destined to interact in solution with the targeted protein for purification, while the second moiety should be able to recognize and bind to a suitable affinity adsorbent. A model system based on this principle has been developed for purifying lactate dehydrogenase (LDH). In this case, the soluble heterobifunctional ligand consisted of the dye CB3GA chemically linked to soya bean trypsin inhibitor, whereas immobilized trypsin is used in an affinity column for binding the soluble complex trypsin inhibitor·CB3GA-LDH.

Continuous Affinity Recycle Extraction

In continuous affinity recycle extraction, instead of packing affinity adsorbent particles in a fixed bed, adsorbent/liquid contact is performed in well-mixed tanks. The adsorbent is continuously circulated between two tanks. Each tank consists of two concentric cylindrical vessels. The wall of the interior vessel is made of a supported filter. The filter porosity is such that it does not allow passage of the adsorbent but only of the liquid stream and its soluble contents, so they can flow through freely. The affinity adsorbent is placed in the space between the concentric cylinders and is continuously recirculated between the two tanks. In one tank there is continuous adsorption of protein to the affinity adsorbent, whereas unbound materials pass through the filter to waste or recycle. In the second tank there is continuous desorption of product from the adsorbent, through the filter, to the collection apparatus. This technique can be applied to dye affinity adsorbents, particularly on a large scale.

Aqueous Two-phase Affinity Partitioning

Affinity partitioning is an inexpensive alternative to affinity chromatography-based purification

technologies, and it is also suitable for large scale application. When aqueous solutions of two high molecular weight polymers, e.g. dextran and polyethylene glycol (PEG), are mixed and then left to settle, depending on the relative molecular mass of the polymers, their concentration and temperature, two phases may be formed: an upper PEG-rich phase and a bottom dextran-rich phase. Under appropriate conditions, many proteins partition to the bottom dextran-rich phase. However, when some of the PEG of the upper phase is replaced by a suitable dye-PEG conjugate, the targeted protein may bind to the dye-PEG conjugate and selectively partition to the upper PEG-rich phase, thus, leading to some purification. An important advantage of affinity partitioning is that the technique can be exploited at the first stage of a purification process, immediately after cell disintegration, without need of centrifugation for prior debris removal. Dye-PEG conjugates have been employed in two-phase affinity systems for partial purification of numerous enzymes, especially those recognizing nucleotides.

Membrane Affinity Filtration

Chemical attachment of the affinity ligand to a filtration membrane provides the principle of the membrane affinity filtration technique. The role of the filter component can be taken by a hollow-fibre microporous membrane where the ligand is chemically attached. The feed stream moves along the interior of the fibre whose pores are large enough (0.5–1.0 μm) to permit convective flow through its body. While binding of the targeted protein to the immobilized ligand occurs without diffusion limitations, unbound substances pass through the fibre body to its outer surface. The main advantage offered by this technique, which is important to industrial-scale purification, is that there is no need for solids removal from the feed stream after cell disintegration. In fact, liquid-solid separation and affinity purification are combined and performed simultaneously when using this technique. Affinity membranes permit rapid processing of large volumes, sometimes even immediately after cell harvesting or disintegration, thus eliminating concentration and partial purification stages. Membrane systems other than hollow fibres have been developed, for example membrane discs and modules of flat membrane sheets bearing immobilized dyes. Such materials are effective tools in protein downstream processing.

Affinity Cross-flow Ultrafiltration

The availability of an affinity macroligand capable of reversible and selective binding of the

targeted protein is essential for applying the technique of affinity cross-flow ultrafiltration. A macroporous membrane is also required which allows passage of the unwanted substances and the targeted protein, but not of the affinity macroligand. When the sample is filtered in the presence of the macroligand, the protein of interest is retained by adsorbing on to the macroligand. During the washing step the targeted protein is desorbed, passes through the membrane and is collected. However, the macroligand will remain retained by the membrane and can therefore be recycled and reconditioned. As with membrane affinity filtration, affinity cross-flow ultrafiltration offers rapid mass transfer, high throughput, and is capable of processing unclarified and viscous materials.

Affinity Precipitation

Affinity precipitation is a bioseparation technique whereby an insoluble network is formed by cross-linking a multifunctional affinity ligand with the protein of interest, thus resulting in selective precipitation of the targeted protein from solution. In principle, such a ligand should be composed of three recognition sites which are able to bind the protein simultaneously. Furthermore, the targeted protein should possess enough ligand-binding sites for the formation of a network. This technique offers certain advantages which are particularly important for large scale purification: no need for solid supports, high ligand utilization, low capital cost, and the possibility of sequential precipitation. True affinity precipitation has been demonstrated for only a few purification cases. An impressive example is the dye structure of **Figure 1(F)**. This nonreactive molecule selectively precipitates and purifies lactate dehydrogenase to homogeneity from crude extract of rabbit muscle. Affinity precipitation has been claimed to occur also with bis-Cibacron Blue 3GA but this technique has not found the anticipated attention.

Instrumentation

Of the techniques described above, dye affinity chromatography and high performance dye affinity chromatography are the main ones employing sophisticated instrumentation. Closed columns (i.e. columns with adapters at both ends) packed with affinity adsorbents can be run and studied with the highest possible precision on automated and computerized chromatography instruments. Such instruments are, for example, the FPLC® System of Pharmacia Biotechnology, and the Waters 650E Advanced

Protein Purification System. Of course, the systems can be used also with nonaffinity chromatography materials. The FPLC® system (pressure limit 4 MPa/580 psi, flow rate range 0.02–8.3 mL min⁻¹) is composed, typically, of a chromatography controller, which offers the facility for connecting to a computer, and controls the rest of the system components: two dual-syringe high precision pumps; a mixing device; an injection motor valve; a sampling loop device to introduce, without dilution, volumes of up to 50 mL; an absorbance detector system with a recorder to monitor column effluents; and a fraction collector with a solenoid valve. Additional motor valves can be used for selecting different liquid phases and columns. The same company also manufactures the BioPilot® system, made especially for exploiting large column beds and processing large sample volumes; it has the similar basic philosophy as the FPLC®. The system offers a flow rate range 0.5–100 mL min⁻¹ at pressures up to 2 MPa/290 psi, and sample volumes up to 150 mL introduced via a loop device. A money-saving alternative to FPLC® offered by Pharmacia Biotechnology, is the GradiFrac™ which incorporates, in a one piece instrument, a fraction collector and a gradient maker. It requires additionally a peristaltic pump, an absorbance monitor, an injection valve, a mixing device, a solenoid valve to form the gradient, and a fraction collector with a solenoid valve. The Waters system is also a nonmetallic liquid chromatograph, operating at flow rate ranges of 0.1–45 mL min⁻¹ or 0.5–80 mL min⁻¹, depending on the pump heads used, having a pressure limit of 750 psi. It is composed of a chromatography and gradient controller which offers the facility for connecting to a computer, a high precision two-head pump, a solenoid four-solvent delivery valve for solvent selection and mixing, a sample injection valve, and an absorbance detector to monitor column effluents. In contrast to the FPLC®, in the 650E system the liquid phase gradient is made at low pressure and prior to entering the pump.

Dye affinity adsorbents based on conventional supports result in low back pressures, when packed in short, wide columns to minimize particle deformation, can be run using peristaltic or other appropriate types of pumps. In contrast, adsorbents composed of small size particles suitable for HPAC (e.g. 5–10 µm) usually need to be run on high pressure instruments, such as those employed in HPLC applications. In this latter case, it is most advisable that titanium pump heads and tubings be used to prevent metal corrosion. However, small size particles with narrow size distribution (e.g. Monobeads®) can be run on

medium pressure instruments (e.g. FPLC® and Waters 650E).

Introduction to Applications

Dyes were originally introduced as cheap alternatives to costly nucleotide ligands for enzyme purification. Given the advantages of dyes over biological ligands, their broad protein-binding spectrum, and also the possibility of improving their selectivity for targeted proteins via molecular modelling, it is no surprise that these colourful tools are finding increasing application in various affinity-based bioseparation techniques. The literature abounds with examples where dye ligands have been employed to purify individual proteins and enzymes: albumin, antibodies, blood-clotting factors, plasminogen activator, proteolytic activities, growth factors, interferons, cellulolytic and lipolytic enzymes, collagenases, restriction endonucleases, and numerous nucleotide-binding proteins and enzymes, to name some examples. It is no exaggeration to claim that for almost every protein purification problem, a dye ligand can be found to help towards its solution.

Hydrophobic Interaction Chromatography

Introduction

According to J.N. Israelachvili (1985), hydrophobic interactions constitute 'the unusually strong attraction between nonpolar molecules and surfaces in water'. For two contacting methane molecules, the attraction energy is about sixfold higher in water than the van der Waals interaction energy in a vacuum. This energy, which has been estimated to be about -8.5 kJ mol^{-1} for two methane molecules is due to the extrusion of ordered water on two adjacent hydrophobic surfaces into less-ordered bulk water with a concomitant increase in entropy. This entropy-driven attraction between nonpolar groups in water is the basis for hydrophobic interaction chromatography.

The chromatographic separation of proteins depends on the differential accumulation of molecules at certain sites within a chromatographic system. Two principal types of chromatographic systems employing hydrophobic media have been described: (a) reversed-phase and (b) hydrophobic interaction chromatography. The principle of reversed-phase chromatography is based on a hydrophobic, e.g., silica, support of very high hydrophobicity which is capable of retaining nonpolar liquid phases (stationary liquid phase) when applied as the less polar phase in a solvent system. In this classical system the solutes are absorbed and separated (partitioned) in the apolar stationary liquid phase (i.e., a three-dimensional system) and not on the solid phase. In hydrophobic interaction chromatography the solutes (proteins) are adsorbed and separated on the apolar stationary solid phase (i.e., a two-dimensional system) carrying

immobilized hydrophobic groups. Because of the very different scopes and methodological details, reversed-phase chromatography will not be treated here. The same holds for other forms of liquid–liquid partition chromatography. A differentiation will also not be made between classical chromatographic systems and HPLC since, in essence, it is only the bead or particle size which leads to the higher performance (e.g. throughput, resolution) in the latter method.

Discovery and Development of Hydrophobic Interaction Chromatography

The chromatographic purification of proteins on specifically synthesized hydrophobic solid supports was first reported independently by Yon and Shaltiel in 1972. In both cases the hydrophobic matrix consisted of agarose to which aminoalkane derivatives have been coupled by the CNBr method. Yon synthesized mixed hydrophobic-charged gels (aminodecyl-, or N-3-carboxypropionyl)aminodecyl-agarose) with an alkyl residue to charge ratio of at least 1 : 1 for the adsorption of lipophilic proteins such as bovine serum albumin or aspartate transcarbamoylase. These proteins were adsorbed at low ionic strength at the isoelectric point and eluted at acidic or alkaline pH by charge repulsion. The surprising result in Shaltiel's experiments was that a very normal hydrophilic enzyme, phosphorylase *b*, could be purified on hydrocarbon-coated agaroses to near homogeneity in one step, implicitly questioning the general doctrine of the time that all hydrophobic amino acids are buried in the interior of proteins. Phosphorylase was adsorbed at low ionic strength on immobilized butyl residues which had no resemblance to the substrates of the enzyme (excluding affinity chromatography) and was eluted by a 'deforming buffer' which imposed a limited conformational change on the enzyme. Taken together with Shaltiel's systematic approach of grading the hydrophobicity of the gels via an immobilized homologous hydrocarbon series, the immediate

impression was that here was a novel method applicable not only to hydrophobic or lipophilic but also to hydrophilic, possibly to all proteins. The name 'hydrophobic chromatography' coined by Shaltiel therefore soon came to widespread use. Only a few months after Shaltiel's first paper, B.H.J. Hofstee published a series of papers leading to similar results.

As stated above, all of these hydrophobic gels were synthesized by the simple CNBr method. Some criticism however arose that positive charges, introduced by a side reaction into the matrix by the CNBr procedure, were influencing the chromatographic results on hydrocarbon-coated agaroses. A rational approach and solution to this problem proved difficult since the chemical mechanism of the CNBr coupling reaction was conclusively clarified only some time later by M. Wilchek in 1981. Wilchek found that the number of charges introduced into the matrix depended on the pH of the washing solution and the length of the washing procedure after CNBr activation of the agarose, since intermediate cyanate esters were selectively hydrolysed in alkali in contrast to the imidocarbonates which were hydrolysed in acid. Thus pure charged isourea gels, pure uncharged imidocarbonate/carbamate gels or mixed ionic-hydrophobic gels can be obtained by the CNBr procedure. In a later paper, Shaltiel conclusively showed that under his conditions the influence of charges in his hydrocarbon-coated agaroses had been small. In addition it was shown by various other groups that salts also effectively quenched the charges introduced by the CNBr method.

Fully uncharged hydrophobic gels were therefore synthesized in 1973 by Porath's group who reacted benzyl chloride with agarose at high temperatures. The synthesis of a graded homologous series of hydrocarbon-coated agaroses was however not possible by this method. In addition Porath demonstrated the inverse salt behaviour of proteins adsorbed on such gels. In contrast to ion exchangers, proteins were applied to these gels at *high salt concentrations* and eluted by decreasing the ionic strength (negative salt gradients). Interestingly the protein cytochrome *c* was adsorbed when 1–3 M NaCl was included in the buffer, a salt which in itself had very little salting-out potential. A similar salt behaviour of protein binding on hydrophobic gels synthesized by the CNBr procedure was reported later by Hjerten who demonstrated that Shaltiel-type gels showed similar properties as the Porath-type gels. Hjerten also suggested the term 'hydrophobic interaction chromatography' which is now popularly accepted. In 1974 Hjerten described a novel preparation of uncharged hydrophobic gels of broad potential by

coupling alkyl and aryl groups via the glycidyl ether method.

In retrospect, although there is no doubt that fully uncharged hydrophobic gels are, by virtue of displaying a single (pure) type of noncovalent interaction, superior to the CNBr-prepared gels, it appears that all groups involved in the development of hydrophobic (interaction) chromatography observed the binding and fractionation of proteins by predominantly hydrophobic interactions. Both terms, 'hydrophobic chromatography' and 'hydrophobic interaction chromatography' can be used synonymously, the shorter term 'hydrophobic chromatography' being no more a misnomer than 'affinity chromatography'.

Fundamentals of Hydrophobic Interaction Chromatography

The Chain Length Parameter

A general systematic approach to the purification of proteins via hydrophobic interactions was initiated by Shaltiel who introduced the principle of variation of the immobilized alkyl chain length in the form of the homologous series of hydrocarbon-coated agaroses (Seph-C_{*n*}, *n* = 1–10). The major conclusion of his experimental result was that an increase of the chain length by –CH₂– units concomitantly increased the strength of protein binding from retardation to reversible binding up to very tight binding ('irreversible' binding). In addition to this variation in binding affinity with the chain length, the gels also changed their specificity towards the adsorbed protein. Thus it was suggested that the properties of hydrophobic agaroses for protein purification could be optimized by variation of the immobilized alkyl chain length.

The Surface Concentration of Parameter

Critical surface concentration of immobilized residues In 1975 we showed that a second parameter is of equal if not greater importance than the alkyl chain length. If, instead of the chain-length, the density (surface concentration) of immobilized alkyl groups is varied, protein adsorption is a sigmoidal function of the surface concentration of immobilized alkyl residues (**Figure 1**) (i.e., surface concentration series). Here also the strength of binding increased from retardation to very tight binding as in the homologous series of Shaltiel. Figure 1 also illustrates the effect of chain elongation in a homologous series which leads to a leftward shift of the sigmoidal curves and to a loss of sigmoidal shape. Another important finding was that a threshold value of the alkyl surface

Figure 1 Dependence of the adsorption of phosphorylase kinase on the chain-length and surface concentration parameters of a homologous series of alkyl-Sepharoses at low ionic strength. The amount of adsorbed enzyme activity per mL packed Sepharose was calculated from the difference between the total amount of applied units and the amount excluded from the gel. The crude rabbit muscle extract or purified phosphorylase kinase was applied to columns containing ca. 10 mL packed gel. The alkyl agaroses were synthesized by the CNBr method. The ratio of alkyl residues to positive charges was ca. 10 : 1. Inset: Double logarithmic plots of adsorbed phosphorylase kinase as a function of the degree of substitution. Experiments with purified phosphorylase kinase are included. A, Seph-C₁: (●) crude extract; (○) purified phosphorylase kinase. B, Seph-C₂: (▲) crude extract; (△) purified phosphorylase kinase; C, Seph-C₄: (□) crude extract. For further details see the text and Jennissen HP and Heilmeyer Jr LMG (1975) General aspects of hydrophobic chromatography. Adsorption and elution characteristics of some skeletal muscle enzymes. *Biochemistry* 14: 754–760.

concentration, a 'critical hydrophobicity', had to be reached before a protein adsorbed. With a ratio of alkyl residues to positive charges in the gels of about 10 : 1, the predominance of hydrophobic interactions as the basis for adsorption was strongly indicated. Thus sigmoidal adsorption curves and critical hydrophobicities could also be obtained in the presence of high salt concentrations (see Figure 2) excluding the argument that the sigmoidal shape was due to the action of charges. Finally, the same sigmoidal behaviour of protein adsorption was found on uncharged hydrophobic gels at low ionic strength and an example will be shown in this article.

Cooperative interaction of multiple immobilized residues with the protein A straightforward interpretation of the sigmoidal curves (Figures 1 and 2) was provided by the concept of multivalence and cooperativity of protein adsorption. It became clear

that the sigmoidicity and the 'critical hydrophobicity' were due to the multivalence of the interaction (i.e., the necessity for a simultaneous interaction of more than one alkyl residue with the protein moiety). The term 'multivalence' is to be preferred to other terms such as 'multiple contacts' since the latter does not differentiate between the binding of a protein to separate alkyl residues or to different segments of one and the same alkyl residue. At high salt concentrations, protein binding displays a positive temperature coefficient in agreement with hydrophobic interactions (see Figure 2). A mathematical model of cooperative protein binding to an immobilized alkyl residue lattice was also developed allowing an estimation of the minimum number of alkyl residues (see Figure 2B) interacting with the protein. The model of multivalence was confirmed by equilibrium binding studies of phosphorylase *b* with alkylamines at high salt concentrations.

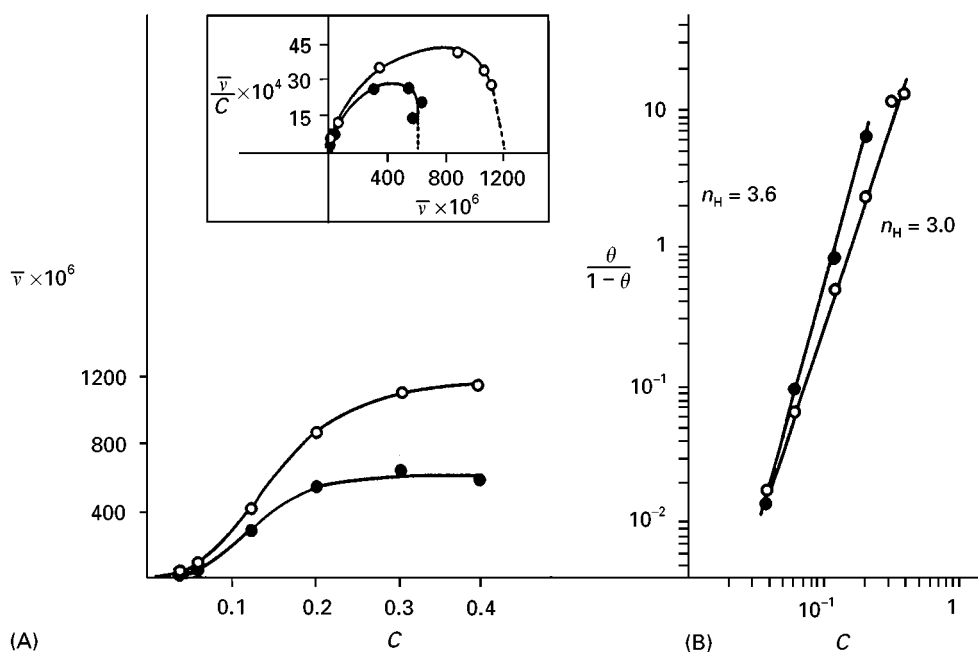

Figure 2 Dependence of the adsorption of phosphorylase *b* on the surface concentration parameter of Seph-C₄ at 5°C and 34°C at high ionic strength. The adsorbed amount of phosphorylase in the presence of 1.1 M ammonium sulfate was calculated from adsorption isotherms measured at each point at an apparent equilibrium concentration of free bulk protein of 0.07 mg mL⁻¹. The adsorbed amount of enzyme (\bar{v}) is expressed in relation to the anhydrodisaccharide content of agarose in mol⁻¹ anhydrodisaccharide. Similarly C indicates the immobilized butyl residue concentration in relation to the anhydrodisaccharide content of agarose in moles of alkyl residue per mole of anhydrodisaccharide. A monomer molecular mass of 10⁵ was employed for phosphorylase *b*. The alkyl agaroses were synthesized by the CNBr method. (A) Adsorption isotherms ('lattice site binding function') of phosphorylase *b* in Cartesian coordinates. Inset: Scatchard plots of the sigmoidal binding curves with extrapolation of fractional saturation of 610 (5°C) and 1220 (34°C) μ moles enzyme per mole of anhydrodisaccharide (corresponding to 6.2 and 13.4 mg mL⁻¹ packed gel respectively). The broken lines indicate the mode of extrapolation. (●) 5°C; (○) 34°C. (B) Hill plots of the sigmoidal binding curves. θ the fractional saturation was calculated from the extrapolated saturation values of the Scatchard plot (A). The Hill coefficients n_H are given in the graph. The apparent dissociation constants of half-maximal saturation ($K'_{D,0.5}$) are 0.137 and 0.167 mole butyl residue per mole of anhydrodisaccharide at 5°C and 34°C respectively (which corresponds to 14.0 and 17.0 μ mole butyl residues per ml packed gel, respectively). (●) 5°C; (○) 34°C. For further details see the text and for the source see Jennissen HP (2000) *Hydrophobic (interaction) chromatography*. In: Vijayalakshmi MA (ed.). *Theory and Practice of Biochromatography*. Amsterdam: Harwood Academic Publishers.

Adsorption hysteresis An important consequence of cooperative multivalent protein binding on alkyl-substituted surfaces is protein adsorption hysteresis. Protein adsorption hysteresis implies that the adsorption isotherm is not retraced by the desorption isotherm, due to an increase in binding affinity after the protein is adsorbed. The binding affinity increase can be attributed to an increase in the number of interactions (multivalence) which can either be due to a reorientation of the protein on the surface or to a conformational change in which buried hydrophobic contact sites (valences) are exposed due to the surface binding strain on the adsorbed protein. Adsorption hysteresis provides evidence for the concept that protein adsorption to multivalent surfaces in general is thermodynamically irreversible ($\Delta_r S > 0$) and that a true equilibrium has not been reached. Another conclusion from this concept is that protein adsorption in hysteretic systems is, moreover, not thermodynamically but kinetically controlled. Thus

adsorption hysteresis has a strong influence on hydrophobic interaction chromatography by leading to nonlinearity and skewed elution peaks in zonal chromatography and to 'irreversibility' in adsorption chromatography. Hysteresis can, however, be easily reduced by decreasing the surface concentration of immobilized alkyl residues.

The Salt Parameter

Salting-out and salting-in on hydrophobically substituted hydrophilic gels The enhancement of hydrophobic interactions by high salt concentrations was first shown by Porath on uncharged benzyl ether agarose and termed a 'salting-out phenomenon'. Trypsin inhibitor could be purified 25-fold after being adsorbed at 3 M NaCl followed by elution in buffer without salt. Proof as to the mechanism and principle underlying these salt effects came in simultaneous, independent reports that the effect of

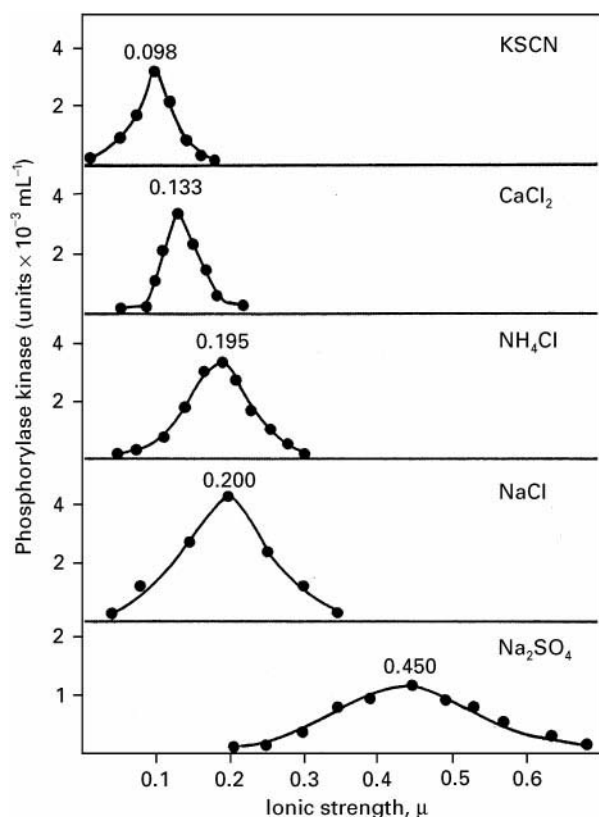

Figure 3 Influence of the salt parameter on the desorption (salting-in) of purified phosphorylase kinase from Seph-C₂ (25 $\mu\text{mol mL}^{-1}$ packed gel) with salt gradients of different ionic composition. Each column with 5 mL of the above gel (CNBr method) was loaded with ca. 11 mg of the enzyme. The gradients were produced from 100 mL low ionic strength adsorption buffer and 100 mL salt containing buffer. The number at the maximum of the elution profiles indicates the ionic strength of the peak fraction. For further details see the text and for the source see Jennissen HP and Heilmeyer Jr LMG (1975) General aspects of hydrophobic chromatography. Adsorption and elution characteristics of some skeletal muscle enzymes. *Biochemistry* 14: 754–760.

salts on the adsorption and elution of proteins on alkyl agaroses indeed followed the Hofmeister series of salts. It could be shown that phosphorylase kinase was eluted ('salted-in') from a Seph-C₂-column by increasing salt gradients. The ionic strength of the peak fractions eluted, was inversely related to the salting-in power of the anions in the gradient in agreement with the Hofmeister series of salts (see **Figure 3**). Similarly proteins could also be eluted (salted-in) from uncharged octyl-Sepharose by an increasing salt gradient of MgCl_2 as shown by Raymond. The opposite effect, namely, the salting-out of phosphorylase *b* by ammonium sulfate on a Seph-C₁-column is shown in **Figure 4B**. The salted-out, i.e. adsorbed enzyme is eluted by omission of this salt from the buffer. Finally Pahlman showed that the salting-out power of anions, for the adsorp-

tion of human serum albumin (HSA) on uncharged Seph-C₅, also followed the order of the Hofmeister series of salts. All of these experiments clearly indicate that the action of the ions was not due to an electrostatic but to a lyotropic effect.

Theories of salt effects One of the earliest approaches to a theory of salt effects was based on the action of chaotropic ions on the solubility of proteins. The general conclusion of this work, with consideration of electrostatic and dispersion forces, was that chaotropes interacted indirectly with solutes (e.g. proteins) mainly through their effect on

Figure 4 Influence of the salt parameter on the adsorption (salting-out) of purified phosphorylase *b* on Seph-C₁ (30 $\mu\text{mol mL}^{-1}$ packed gel). The equilibration buffer contained 10 mM sodium β -glycerophosphate, 20 mM mercaptoethanol, 2 mM EDTA, 20% sucrose, 0.5 μM PMSF, pH 7.0 (buffer B) to which either 1.1 M ammonium sulfate or NaCl was added. 6 mg per 3 mL phosphorylase *b* was added to 20 mL Seph-C₁ in a 2 cm i.d. \times 17 cm column. Fractions of 6.5 mL were collected. The gel was prepared by the CNBr procedure. (A) Application of enzyme to a column equilibrated with buffer without $(\text{NH}_4)_2\text{SO}_4$ or NaCl: (1) application of phosphorylase *b* in buffer B; (2) elution with buffer B + 1 M NaCl. (B) Application of enzyme to a column equilibrated with buffer with $(\text{NH}_4)_2\text{SO}_4$: (1) application of phosphorylase *b* in buffer B + 1.1 M ammonium sulfate; (2) elution with buffer B; (3) elution with buffer B + NaCl. For further details see the text and for the source see Jennissen HP (2000) Hydrophobic (interaction) chromatography. In: Vijayalakshmi MA (ed.). *Theory and Practice of Biochromatography*. Amsterdam: Harwood Academic Publishers.

water structure. In the solvophobic approach of Horváth the surface tension of water was also of central importance. The energy necessary for bringing a solute into solution was equated with the energy needed for forming a corresponding cavity in water against the surface tension with a reduction in free volume. The net free energy involved in the association of two molecules was thus related to a reduction of the cavity size. Salting-in and salting-out were explained on the basis of the respective surface tension-decreasing/-increasing effect of the salt which was applicable to reversed-phase chromatography as well as to hydrophobic interaction chromatography. Finally, according to Arakawa (1984, 1991) there also do appear to be specific salt effects resulting from a direct binding of salt ions (e.g. of MgCl_2) to the protein.

Irrespective of the mechanism, the applicability of the Hofmeister (lyotropic) series of salts expanded by the chaotropic series, to hydrophobic interaction chromatography has been verified by many groups and these salts are important tools in controlling the adsorption and elution of proteins on these resins. The individuality of each protein in its quantitative interactions in such a system especially when in the native state should, however, not be underestimated.

Optimization of Hydrophobic Chromatographic Systems

Twenty years after the introduction of hydrophobic interaction chromatography, the method has not gained the same foothold in the methodological repertoire of protein chemistry as has affinity chromatography. Although a large number of proteins have been successfully purified by this method a recent paper by Oscarsson *et al.* comes to the conclusion that certain 'classical' commercial hydrophobic adsorbents are inadequate for ideal downstream processing because of their high hydrophobicity. The criticism of these authors is essentially correct. The major problem encountered on such hydrophobic gels is that proteins can be very effectively adsorbed but elution in the native state is often impossible. Although a similar problem can be encountered in affinity chromatography, it appears to be the major handicap in hydrophobic interaction chromatography and must be taken into account in any general optimization procedure.

The Homologous Series Method

Shaltiel's homologous series method of synthesizing hydrocarbon-coated agaroses was supplemented by

the so-called exploratory kit, for choosing the most appropriate column and for optimizing resolution. This analytical kit, which was commercially available for some years, contained a homologous series of small columns from Seph-C₁ to Seph-C₁₀ with two control columns. The principle was to determine the lowest member of the homologous series capable of retaining the desired enzyme or protein. This column was then selected for the purification of the desired protein. In a second step it was attempted to increase resolution by optimizing the elution procedure which ranged from mild salting-in procedures to reversible denaturation steps. This procedure or variants thereof are still the method of choice for most groups. However as illustrated by Oscarsson *et al.*, the number of failures is probably very high.

The Critical-Hydrophobicity Method

As stated above there are two methods for the synthesis of controlled hydrophobicity gels (a) via the homologous series of hydrocarbon-coated Sepharoses (variation of alkyl chain length) or (b) via the concentration series (variation of the alkyl surface concentration). The importance of the latter series has been underestimated. Both gel series essentially correspond to members of 'hydrophobicity gradients'. Although the decisive importance of the immobilized alkyl residue concentration for the hydrophobic adsorption of proteins (critical hydrophobicity) has been stressed for many years, no hydrophobicity gradient gel series has ever been produced commercially. Against the background of obvious problems in hydrophobic interaction chromatography, a novel rational basis for the optimization and design of such chromatographic systems has been suggested.

High yields in hydrophobic interaction chromatography can only be obtained if the protein to be purified is fully excluded from the gel under elution conditions as near as possible to physiological conditions, i.e., at low ionic strength. This means that the gel should be fully non-adsorbing under these conditions. On the other hand, since a purification is only possible if the protein is adsorbed to the gel, the matrix should be constructed in a way that adsorption can be easily induced by other means without denaturing the protein. Thus working at, or near to the critical hydrophobicity point, could solve both problems. In the synthesis of such critical-hydrophobicity gels the charge-free immobilized residues should be restricted to alkane derivatives, to ensure a 'purity' of hydrophobic interactions. NaCl, centrally located in the Hofmeister series, appears to be ideal. The procedure involves three steps: (i) selection

of an appropriate alkyl chain length, (ii) determination of the critical surface concentration of alkyl residues (critical hydrophobicity), and (iii) determination of the minimal salt concentration (NaCl) necessary for the complete adsorption of the protein. The three parameters are determined by a form of quantitative hydrophobic interaction chromatography utilizing primarily the high-affinity adsorption sites.

Selection of the appropriate alkyl chain length In the first step, an experimental setup similar to the homologous series method of Shaltiel is employed to gain information on the general hydrophobic binding properties of the protein and columns. However it is essential that a quantification of the immobilized surface concentration has taken place at this stage. Gels of $20\text{--}25\ \mu\text{mol mL}^{-1}$ packed gel appear optimal. In general a constant amount of protein (ca. $0.5\ \text{mg mL}^{-1}$ packed gel, which can be 100% adsorbed on the column of highest hydrophobicity) is applied at low or physiological salt concentration to each column (1–2 mL packed gel). One then determines the gel in the homologous series which adsorbs ca. 50% of the applied protein. In the case of the example below, ca. 50% of the applied fibrinogen was adsorbed on an uncharged Seph-C₅ gel containing $22\ \mu\text{mol mL}^{-1}$ packed gel.

Determination of the critical hydrophobicity As previously defined, the critical hydrophobicity is that degree of substitution at which adsorption of a protein begins. As shown in Figure 5 a strongly sigmoidal adsorption curve of fibrinogen is obtained on the concentration series of uncharged Seph-C₅ gels at a physiological NaCl concentration. The aim is to get as close as possible to the critical hydrophobicity point with a minimum of adsorbed protein. Since there was no measurable adsorption of fibrinogen at $12\ \mu\text{mol mL}^{-1}$ packed gel and only ca. 2% was adsorbed at $13.6\ \mu\text{mol mL}^{-1}$ packed gel (critical hydrophobicity), the ideal juxtacritical hydrophobicity range for fibrinogen was taken as $12\text{--}14\ \mu\text{mol mL}^{-1}$ packed gel.

Determination of the minimal salt concentration (NaCl) necessary for adsorption In experiments with NaCl concentrations between 0.5 and 5 M, it was found that all of the applied purified fibrinogen was adsorbed on Seph-C₅ of a residue surface concentration of $13.6\ \mu\text{mol mL}^{-1}$ packed gel at a salt concentration of 1.5–1.6 M NaCl. The salt concentration necessary for half-maximal adsorption was ca. 0.75 M NaCl. Since no (i.e., 2%) fibrinogen was

Figure 5 Determination of the critical surface concentration (critical hydrophobicity) of Seph-C₅ for the adsorption of purified fibrinogen. The uncharged pentyl agaroses were synthesized by the carbonyldiimidazole method. Purified human fibrinogen (1 mg) was applied in 1 mL to a column (0.9 cm i.d. \times 12 cm) containing 2 mL packed gel in 50 mM Tris/HCl, 150 mM NaCl, 1 mM EGTA, pH 7.4. Fractions of 1.5 mL were collected. The column was washed with 15 mL buffer followed by elution either with 7.5 M urea or, at high hydrophobicity of the gel, with 1% SDS for the determination of the amount of protein bound. 100% equals 1 mg fibrinogen adsorbed to 2 mL packed gel of Seph-C₅. The total amount of adsorbed fibrinogen, corrected for the amount adsorbed to unsubstituted control Sepharose 4B, is shown. For further details see the text and for the source see Jennissen HP (2000) Hydrophobic (interaction) chromatography. In: Vijayalakshmi MA (ed.). *Theory and Practice of Biochromatography*. Amsterdam: Harwood Academic Publishers.

adsorbed to this pentyl Sepharose at low ionic strength, a complete recovery of fibrinogen adsorbed under these conditions is now possible by decreasing the salt concentration. Thus the critical hydrophobicity gel together with NaCl constitutes a fully reversible hydrophobic adsorption system for fibrinogen.

One-step purification of native fibrinogen from human blood plasma Employing Seph-C₅ of critical hydrophobicity equilibrated with 1.5 M NaCl it is possible to purify fibrinogen from human plasma in a single step (Figure 6). The procedure is so robust that fibrinogen can be purified from human blood plasma directly (no dialysis) in spite of a temporary decrease in NaCl concentration (fractions 5–9) during the run. After extensive washing with 1.5 M NaCl ca. 20-fold purified pure fibrinogen

Figure 6 One-step purification of fibrinogen from human blood plasma by hydrophobic interaction chromatography at the critical hydrophobicity point of Seph-C₅. (A) 19 mL fresh unclotted human blood plasma was applied (arrow 1) to 20 mL packed Seph-C₅ (13.6 $\mu\text{mol mL}^{-1}$ packed gel in a column 1.4 cm i.d. \times 13 cm) equilibrated with 50 mM Tris/HCl, 1.5 M NaCl, pH 7.4 at a flow rate of 70 mL h⁻¹ and a fraction volume of 6 mL. The nonadsorbed protein was washed out with 200 mL equilibration buffer. Elution (arrow 2) was facilitated by equilibration buffer containing a tenfold lower salt concentration of 150 mM NaCl. (B) The fractions 30–32 contain pure fibrinogen with a clottability of 93–100% with a total yield of 25%. For further details see the text and legend to Figure 5 and for the source see Jennissen HP (2000) Hydrophobic (interaction) chromatography. In: Vijayalakshmi MA (ed.). *Theory and Practice of Biochromatography*. Amsterdam: Harwood Academic Publishers.

(clottability 93–99%; Figure 5) is eluted by a negative step gradient from 1.5 to 0.15 M NaCl. The total yield is 25% with some loss in the run-through. Yields of fibrinogen of up to 60% have been obtained. If blood plasma equilibrated with 1.5 M NaCl is applied to the gel and eluted by a negative salt gradient, a clottability of 80% is obtained (Figure 6).

Conclusions

From the foregoing it can be concluded that hydrophobic interaction chromatography is one of the very basic separation methods in classical biochemistry. A great deal of information on the mechanisms involved in the method has been obtained and it appears that the critical hydrophobicity method

for the optimization of hydrophobic supports offers a rational approach to the purification of proteins. The only drawback is that such hydrophobic gel series are not commercially available so that the application of this method necessitates experience in the synthesis of alkyl agaroses and the quantification of immobilized residues. Methodological investments of this types thus pose the 'high-energy barrier' to a more widespread and successful application of hydrophobic interaction chromatography in enzymology and protein chemistry.

Immobilized Boronates/Lectins

W. H. Scouten, Utah State University,
Logan, UT, USA

Copyright © 2000 Academic Press

Lectins and boronates have affinity for very similar biological compounds. They are both useful for separating glycoproteins, glycolipids, and other glycosylated compounds as well as for the separation of sugars and, in the case of boronates, other compounds containing appropriate 1,2 or 1,3 diols. There is, however, a fundamental difference between lectins and boronates. Lectins bind to glycosylated molecules because of a natural biological interaction between the lectin and the sugar moiety of the glycosylated compound. Lectins have biological purposes and functions related to this sugar-lectin interaction. On the other hand, boronates have no biological function but serve as a compound which, by chemi-selection, binds to 1,2 or 1,3 vicinal, co-planar, diols. Since many sugars contain such diols, boronates are very useful functioning as a 'chemical lection'. However, lectins have a much higher degree of binding specificity, as would be expected from the fact that biological interactions depend on multiple binding sites and intricate interactions with complex stereochemistry. Thus, any given lectin may bind to a specific sugar; or in other cases, may bind to an array of sugars. Thus, there exists a broad repertoire of lectins that are capable of binding to various types of glycosylated biomolecules. Fortunately, a sufficient number of lectins are available commercially to provide essentially the entire array of binding sites and, certainly, that array which is needed for biological separations of glycosylated biomolecules.

The corollary to this is that while boronates have a fairly low degree of specificity, they have a much higher stability than lectins. Thus an immobilized boronate, such as a boronate chromatography matrix, can be stored for years, whereas a lectin may have limited storage and operational stability.

Finally, in lectin affinity chromatography it should be understood that lectins are purified by affinity chromatography on a variety of immobilized sugars. Such 'reverse' lectin chromatography is beyond the scope of this discussion but does provide a methodology for identifying and isolating lectins that have a unique specificity for a particular rare combination of one or more sugar molecules.

Applications

None of these can be considered *the* application for lectin or boronated chromatography. By far the largest application of both is in the separation of glycosylated haemoglobin from non-glycosylated haemoglobin for diagnosis of diabetes (see below).

Other diagnostic applications for both lectins and boronates have been proposed. In particular, lectins have been used to bind proteins associated with specific forms of cancer. These have the potential to be developed into useful diagnostic procedures.

In addition, both lectins and boronates have the potential to be used in large-scale purification of various glycosylated proteins and other glycosylated biomolecules for commercial purposes. Since most extracellular mammalian proteins are glycosylated, and since many of these have useful commercial value, boronate chromatography is likely to develop into a significant tool for commercial purification.

Basic research also utilizes affinity chromatography based on lectins and boronates. Lectins are far more commonly utilized when the goal is to identify different glycosylated isoforms of particular proteins or to determine which oligosaccharides are present on the surface of the cells and organelles. Utilizing successive chromatography with a bank of lectins of various specificities, coupled with glycosylases with distinct and varied specificities, the entire sequential composition of oligosaccharides can be readily determined.

Other uses, of course, exist for lectin and boronate chromatography; for example, the purification of specific organelles or cells utilizing the sugar moieties of glycosylated proteins forming the membrane surface of the organelle and/or cell.

Problems or Pitfalls

There are numerous difficulties with any type of chromatography. Perhaps the foremost is the expectation from a method containing the word 'specific' that one will obtain a highly purified material in a single chromatographic step. Occasionally this can be true, but far more commonly either lectin or boronate chromatography is just one of several steps needed to obtain a reasonably pure product. The true advantage of these two chromatographic methods, however, is that they complement standard chromatographic methods such as ion exchange, gel permeation and hydrophobic chromatography.

Among the other problems associated with boronate and affinity chromatography is that the binding of molecules to a particular lectin or boronate can only be determined by trial and error. This calls for a fairly large pilot study which employs various lectins and/or boronate derivatives bound to various matrices and at several ligand concentrations. Without this information, it is difficult to optimize the separation; nevertheless, simple separations are sometimes done by taking a commercial immobilized lectin off the shelf and attempting a full chromatographic separation. In most cases, this is done with a concanavilin A stationary phase, since Con A is relatively inexpensive, fairly stable, and has a broad specificity for a number of saccharide moieties. Thus it has a high probability of effecting a reasonable separation of glycosylated molecules from nonglycosylated molecules or from molecules which are glycosylated in significantly different ways. Con A has a primary binding to glucose or mannose moieties which are, fortunately, very common terminal sugars in glycosylated proteins.

An additional problem found in affinity chromatography is nonspecific binding. Both the lectin itself and the alkyl portion of the boronate can be the source of nonspecific binding.

One final problem with lectin chromatography is the high toxicity of some lectins. The reader should be warned that some lectins are highly toxic and must be handled with extreme caution, although others have little or no toxicity.

Applications of Boronate Chromatography

The interaction of boronate with low molecular weight compounds has been known since the mid-nineteenth century when it was first observed by Biot. Since then this interaction has been employed for the separation of many biologically important vicinal diols, particularly monosaccharides, polysaccharides and various glycosylated macromolecules. The earliest applications involved the separations of various sugars. Boronate forms a charged complex with a sugar diol and, occasionally, a bridge compound in which two sugar molecules are bridged by a single boronate. These complexes can be separated from one another and from unchanged molecules by ion exchange chromatography. Boronate in elution media converts normally neutral sugar molecules into an ionic component in which the charge eventually is dependent upon the structure and stability of the boronate-sugar complex.

A variation of this is boronate affinity chromatography, in which a boronic acid is coupled by

means of a spacer organic molecule to an appropriate matrix. The most widely used is *m*-aminophenylboronic acid, which has been coupled with agarose, polyacrylamide gel and beaded cellulose, among other matrices. In this case, the sugar will bind to the boronate matrix and can be eluted using appropriate elution conditions. Binding is generally aided by an alkaline pH at a fairly high ionic strength, since the resulting complex between the bound sugar and the immobilized boronate is negatively charged and high ionic strength stabilizes the charged spacer. Elution can be readily effected using mildly acidic or neutral pH and a low ionic strength eluent.

Separation of sugars on boronate affinity matrices has been little utilized and is of only minor importance. On the other hand, the separation of many biological macromolecules containing sugars is of extreme significance. Nucleosides, nucleotides, catecholamines and tRNA are among the more important compounds which have been separated by this method.

The most important separations that have been performed on boronated affinity chromatography are those of glycosylated proteins, including glycosylated enzymes. Most proteins exported from cells are glycosylated prior to their secretion. This glycosylation has been observed to be of significance in determining the lifetime of, for example, a serum protein, as glycosylases remove the sugar residues until a nearly sugar-free molecule is recognized by liver cells and removed from the blood stream by phagocytosis.

Many proteins which are naturally glycosylated in mammalian tissue are produced in recombinant microorganisms in a nonglycosylated form. While many of these have utility in a research laboratory, there is considerable reluctance to utilize human proteins without normal glycosylation as therapeutic materials; therefore, many of these mammalian proteins are now produced by recombinant systems in organisms which glycosylate the proteins in a way that mimics their natural glycosylated state. For this reason, determination of the oligosaccharide structure of glycosylated residues is very important. As will be seen in the following section, this is done chiefly using lectin chromatography. Boronate chromatography, on the other hand, provides a general way in which glycosylated proteins can be purified and separated from nonglycosylated proteins and often other glycoproteins. The interactions between the matrix and the glycosylated proteins need to be minimized, while the chemi-selective adsorption of the sugar diols to form diesters with the boronate needs to be maximized. To do this, the chromatography must be done under conditions in which the pH is reasonably high, usually above the pK of the boronate, and, at the same time, the ionic

strength must be high enough to suppress the ion exchange properties of the naturally charged boronate residues. At the same time, too high ionic strength will increase hydrophobic interactions between the protein to be purified and the matrix on which the boronate residue is bound or the organic molecule which bears the boronate, for example the phenyl portion of the *m*-aminophenylboronic acid. To accomplish both of these goals simultaneously, normally a cation such as magnesium is employed. Magnesium is effective at suppressing the boronate charge at relatively low concentrations, which do not significantly promote hydrophobic binding of the protein to the matrix. Many glycosylated proteins and enzymes can be separated from their nonglycosylated counterparts in a single chromatographic step, which, while not always producing a homogeneous protein, effects considerable purification and selection.

By far the most important boronate separation is the separation of glycosylated haemoglobin from its nonglycosylated counterpart. Glycosylated haemoglobin is created in a very different fashion from the biological glycosylation of secreted proteins. Haemoglobin produced within the red blood cell is not glycosylated; however, in a nonenzymatic process, amine residues of the haemoglobin react with glucose and form a transient Schiff's base. This Schiff's base then undergoes a rearrangement (the Amadori rearrangement) to produce a stable fructosamine derivative of the haemoglobin molecule. The rate at which this reaction occurs and thus the percentage of haemoglobin which is glycosylated, is totally dependent upon the concentration of glucose in the blood stream. Since the haemoglobin molecule has a half-life of approximately 60 days in the blood stream, the percentage of glycosylated haemoglobin provides a good measure of the long-term average blood glucose concentration. By separating the glycosylated haemoglobin from nonglycosylated haemoglobin, the physician has a diagnostic tool for the diabetic management of patients. Diabetic patients notoriously mis-report their exercise and adherence to dietary prescriptions of the physician. By taking a small sample of blood and separating the diabetic, or glycosylated, haemoglobin from nondiabetic, or nonglycosylated, haemoglobin, a reasonable measure of the history of the patient's serum glucose levels can be achieved. This is a very widely used test of great significance in the control of this important disease. Proteins, other than haemoglobin, could be utilized for this assay, since other serum proteins such as serum albumin undergo nonenzymatic glycosylation. Glycosylated haemoglobin is the most readily measured in a reliable fashion and has, to date, provided the physician with the best diagnostic methodology.

In addition to the diabetic analysis, boronate chromatography has the potential to form the basis of other significant diagnostic assays, such as assays for catecholamines, as well as for various differences in protein composition and nucleoside concentrations in various tumours. This potential has not yet been fully realized.

Lectin Chromatography

Immobilized lectins are true complements to boronate chromatographic materials. Lectins do not have the stability that boronates possess, but they possess a considerably higher and broader range of specificity. While there are several immobilized commercial boronate materials available for boronate affinity chromatography, there are a much greater number of different types of immobilized lectins. For example, one commercial firm offers 19 different lectins immobilized by several different methods, chiefly to agarose. The same firm offers approximately 60 purified lectins in a nonimmobilized state, any one of which could be immobilized by a researcher for his or her own specific purposes. Since the specificity of lectins can vary from relatively narrow specificity to those which have very broad specificities, and since the specificities between lectins are so varied, they offer a very powerful tool for separating many glycoproteins. An idealized purification scheme utilizes boronate affinity chromatography in an initial purification step, which allows one to obtain first the glycosylated protein fraction as a whole, followed by lectin affinity chromatography to separate the glycosylated proteins.

Lectins are obtained from either plant or animal materials and have various biological functions. Originally, lectins were also termed phytohaemagglutinins because they were isolated from plant sources (phyto) and were used to classify blood cells by their agglutinating property (haemagglutinins). The agglutination occurs because lectins are multimeric proteins with multiple sugar binding sites which can crosslink red blood cells, thus aggregating them.

There are two basic approaches to lectin affinity chromatography. At the present time, the easiest approach, and the one most commonly used, is to survey the commercially available lectins, preferably those which are already immobilized, for their ability to bind the target protein. It is helpful if the terminal sugar of the glycosylated protein is already known, since that makes the choice of lectin much easier. On the other hand, it is also relatively simple to carry out a trial and error procedure to determine which immobilized lectin is best in the purification of a particular

protein. It is also possible to immobilize an appropriate lectin from among the many commercial lectins that are available if the terminal sugars of the glycoconjugate to be purified are known.

The second approach is to determine the terminal sugar of the glycoconjugate to be purified and then to purify, *de novo*, a new lectin, by immobilization of the desired terminal sugar to a matrix, such as agarose, by means of a spacer arm. This allows the screening of numerous potential lectin sources to find as many lectins as possible that will bind to the target sugar. This methodology was used for many years prior to the present significant commercial availability of purified lectins.

After the lectin has been chosen and obtained in an immobilized form, or is immobilized by one of many simple procedures, for example agarose or cyanogenbromide-activated agarose, or Affi-gel 10, adsorption/desorption, method conditions need to be defined. The binding of glycoproteins to lectins is generally easier than their elution. The factors in binding are generally temperature and salt concentration, as well as the density of coverage of the lectin immobilized on the matrix. High densities of lectins are not desirable in most instances. Although high ligand density may yield a marginal increase in capacity, it significantly increases the difficulty of eluting the target protein. The use of a moderate salt concentration is often helpful during binding of the glycoprotein target to the immobilized ligand. In many instances, it is necessary to be certain that the required metal ions are included in the sample wash and elution buffers in order to prevent deforming and/or denaturation of the lectin. Once the protein binding conditions have been determined, elution conditions need to be investigated. If one wants to have the highest purity product and to be certain that binding the protein to the immobilized lectin is through the biologically significant, sugar-protein interaction, then elution should be done by a high concentration of the free sugar. This will bind competitively to the lectin, displacing the glycoconjugate and thus eluting it. The sugar concentration during elution must be high enough to compete effectively with the lectin for the glycoconjugate, particularly when the density of the immobilized lectin is high.

Nonspecific elution of the glycoprotein from the lectin is frequently used. Changes in pH, temperature and salt can affect elution by decreasing the affinity of the lectin for the glycoconjugate. If elution were either with free sugar or by changing binding conditions, for example pH, a good yield is not obtained. It is also possible to apply an eluent to the column and stop the flow, thus allowing equilib-

rium to be reached in the free solution. This may or may not be necessary, however, and frequently a simple clean elution can be obtained by a proper choice of conditions.

One of the more interesting applications of immobilized lectins is the determination of the structure of sugar residues bound to the glycoconjugate. For example, a protein will be applied to a specific immobilized lectin and found to bind to that lectin. If the lectin has a rather broad specificity, the investigator cannot be certain which sugar is the terminal sugar on the oligosaccharide moiety of the glycoprotein. However, by using various glycoses to remove the terminal sugar, the investigator can determine which glycase yields a derivative that will no longer bind to the immobilized lectin used. The glycase specificity indicates the identity of the terminal sugar. This procedure can be done repetitively and from the results a reasonable understanding of the structure of the oligosaccharide of the glycosylated protein can be determined.

Conclusion

Both boronate chromatography and lectin affinity chromatography have considerable potential for future use in biotechnology. Proteins with proper glycosylation are becoming more and more important because it is perceived to be desirable to have proper glycosylation for therapeutic purposes. In addition, researchers are becoming more and more aware that the structures of oligosaccharides bound to glycosylated proteins contain valuable information on the biological system from which the protein was isolated. It appears that both boronate and affinity chromatography will be valuable in basic research and in commercial protein purification and undoubtedly for other applications as yet unknown.

Introduction

Since its introduction by Porath in 1975, immobilized metal ion affinity chromatography (IMAC) has developed into a robust and versatile tool. The number of uses is large and includes the isolation of metal-binding compounds from sea water, separation of enantiomeric forms of amino acids, tetracycline removal from animal products and protein purification. This article will focus on its application to protein purification, where it relies on the ability of certain amino acid side chains to form coordinative interactions with immobilized metal ion chelate complexes. As a chromatographic method it falls somewhere between biospecific affinity chromatography and ion exchange chromatography. The evolution of the technique, current tools and some specific technical details are discussed.

Background

Knowledge of the interaction of metal ions with proteins and the potential utility of immobilized metal chelators began during 1940–50, although it was not until 1974 that the method was first used to isolate a metalloprotein. The general use of IMAC was initiated in 1975 with a *Nature* publication from Porath. A summary of key milestones in the history of IMAC is presented in Table 1.

In the late 1970s and 1980s there were numerous publications on the choice of metals and investigations on the precise nature of the interactions that take place with proteins. It was assumed that surface-exposed residues were coordinating with the immobilized metal ions. Studies using free amino acids, peptides, and eventually engineered recombinant proteins, revealed the importance of certain amino acids

– in particular histidine. Additionally, depending on the metal and chelating ligand employed, the spatial arrangement of the amino acids within the peptide or protein was also found to influence binding. This led to studies using model peptides with a wide range of histidine-containing sequences and in 1988 the first use of six consecutive histidine-residues as a purification tag (6His tag). In parallel with this 1987 saw the introduction of a metal–chelate complex with a high degree of selectivity for adjacent histidine residues (Ni^{2+} –NTA). Proteins purified using the 6His tag have been found to retain biological activity and their structures have also been solved by both X-ray and NMR – illustrating that, in the absence of metal ions, the tag has no defined secondary structure. Despite the enormous utility of the 6His tag the use of metal chelating ligand/metal combinations still has a role to play in the isolation of nontagged proteins from a wide variety of sources. The literature contains many examples of using IMAC as a one-step process to isolate native proteins, e.g. α -lactalbumin from milk and factor IX from blood. In addition, immobilized Fe^{3+} has been successfully used to separate phosphoproteins and immobilized Ca^{2+} to purify calcium-binding proteins.

The potential exists for even wider application to the separation of protein mixtures, with new chelators being introduced (e.g. TACN, see below).

TREN	Tris(2-aminoethyl)amine	4	$\sim \text{NHCH}_2\text{CH}_2\text{N}(\text{CH}_2\text{CH}_2\text{NH}_2)_2$
Talon	Proprietary	4	Proprietary
TED	Tris(carboxymethyl)ethylenediamine	5	$\sim \text{N}(\text{CH}_2\text{COOH})\text{CH}_2\text{CH}_2\text{N}(\text{CH}_2\text{COOH})_2$

~ Indicates chosen form of linkage to a chromatographic support, usually with a suitable spacer.

– Indicates atoms involved in metal ion coordination.

Whether purifying proteins using native exposed histidines, post-translation modifications with phosphate or via an engineered 6His tag, IMAC provides a versatile and relatively gentle method with the potential to provide greater than 90% purity in a single chromatographic step.

Components

Metal Ions

A search of the literature on IMAC reveals a bewildering array of metal ions that have been used in this technique (e.g. Ag^+ , Al^{3+} , Ca^{2+} , Co^{2+} , Cr^{3+} , Cu^{2+} , Eu^{3+} , Fe^{3+} , Hg^{2+} , La^{3+} , Mn^{2+} , Nd^{3+} , Ni^{2+} , Yb^{3+} , Zn^{3+}). The reason for this is that the nature of the metal ion (and indeed its chelator) influences the selectivity and affinity of the protein interaction. The most commonly used metals can be grouped into the 'hard' and 'soft' types – reflecting their electron orbital configuration and ability to act as electron acceptors. In free solution the metal ions exist with a shell of water molecules. Upon chelator or protein binding the water is displaced and a coordination bond to the metal ion is formed by the donation of free electron pairs from atoms in the chelator or in the amino acids (e.g. N, O and potentially S) of the protein. As such the atoms behave as monodentate ligands with the affinity estimated to be in the micromolar range. Both the protein and the immobilized chelator have the potential to be polydentate. For protein binding the 'soft' metal ions (e.g. Cu^{2+} , Co^{2+} , Zn^{2+} , Ni^{2+}) show a preference for coordination with nitrogen-containing functional groups such as the imidazole of histidine (either δ or ϵ nitrogens). The 'hard' metal ions (e.g. Al^{3+} , Ca^{2+} , Fe^{3+}) show a preference for oxygen-containing groups such as carboxyls or phosphates found in phosphorylated proteins. These preferences are exploited in the nature and types of proteins purified with particular

combinations of chelator and metal ion, and, to a certain extent, with the choice of buffer conditions. Within the 'soft' metal group a rank order of affinity for histidine residues has been established. In increasing strength of binding this order is $\text{Co}^{2+} \approx \text{Zn}^{2+} < \text{Ni}^{2+} < \text{Cu}^{2+}$. Histidine is relatively rare, representing only 2.2% of the amino acids across all proteins with many containing none or none accessible on their surface. This provides a built-in selectivity for certain native proteins. The use of genetic engineering to introduce a 6His tag further exploits the selectivity for histidine. The preferred use of Ni^{2+} in IMAC with 6His tagged proteins is in part due to its higher coordination number ($\text{Cu}^{2+} = 4$, $\text{Ni}^{2+} = 6$) and the fact that the weaker binding potential of the Ni^{2+} is compensated for by the tag, thus providing an even greater degree of selectivity over other proteins from the recombinant host.

Chelating Ligands

Metal chelators bound to chromatographic media fix the metal ion to a solid support, enabling the separation process to take place. They modulate the affinity and selectivity of the chromatographic matrix as well as its capacity for proteins. A relatively large number of such ligands exists in the literature, although only a subset of these have found routine use in IMAC. This discussion limits itself to the most common chelating ligands and new developments in the area. Table 2 presents a summary of the properties for a selection of chelating ligands.

During the design of chelating ligands several factors have been taken into consideration. Increasing the dentation number of the chelator will increase its affinity and reduce unwanted metal ion leakage from the column. Counterbalanced with this is the need to provide free coordination sites for the protein with binding capacity and affinity increasing as the number of these sites increases. In addition, metal ion transfer must be avoided, i.e. the chelating ligand

must bind the metal ion sufficiently tightly so as not to be stripped by proteins in the mixture to be purified.

As a consequence of the above considerations, several chelating ligands have been developed and successfully used in IMAC. **Figure 1** shows a schematic representation of the octahedral coordination of a metal ion (e.g. Ni^{2+}) with the chelators IDA, NTA and TED, illustrating the decrease in available protein-binding sites as the dentation of the chelator increases. IDA was the chelating ligand used by Porath in the first publication on IMAC in 1975. While adequate for the purpose, and still used today, this ligand is only tridentate and metal ion leakage can be a problem. When complexed with Cu^{2+} only one coordination site remains for protein binding. With Ni^{2+} , while three free coordination sites are available for protein binding, the metal binding is

often too weak for practical use. For these reasons NTA was developed by Hochuli as an alternative to IDA. As shown in **Figure 2** the structure of NTA is closely related to that of IDA. NTA chelate with the oxygens of three carboxyl groups and a nitrogen, while IDA uses just two carboxyl groups and a nitrogen. The tetradentate nature of NTA means that metals other than Cu^{2+} must be used. When complexed with Ni^{2+} , two coordination sites are available for protein binding. The increased stability and coordination potential of NTA-based matrices has provided remarkable selectivity, especially when combined with recombinant proteins with engineered histidine tags. This combination was first introduced commercially by Qiagen.

To further address the issues of stability, selectivity and capacity, several alternative tetradentate

Figure 1 Schematic representation of IDA and NTA metal chelation.

Figure 2 Ni^{2+} -NTA chelation and binding of consecutive histidine residues.

chelating ligands have also been developed and used successfully, e.g. TREN coupled to a high capacity matrix (Novarose-Inovata AB) for the rapid purification of goat immunoglobulins and Talon (Clontech) as a Co^{2+} loaded support which claims even higher selectivity in the isolation of 6His tagged proteins. TACN has recently been introduced and used with a range of 'soft' metal ions. This chelator exhibits remarkable metal-binding stability at low pH, where other chelators would exhibit loss of the metal. This extended pH range could be used to gain further selectivity. The pentadentate TED offers very tight metal ion binding and highly selective protein binding. In addition, the strength of metal ion binding to TED can be exploited as a second column to remove potentially leached metal ions from other IMAC eluates.

Media

The first commercially available IMAC medium was IDA-Sepharose (AP Biotech). Today, many IDA-chelating media are available, including modified forms of Sepharose (AP Biotech), agarose, polystyrene, polystyrene/divinylbenzene (Poros-Perseptive Biosystems), poly(alkalhydroxy-methacrylate), silica and even magnetic polystyrene beads (Dynabeads, Dynal Inc.). Among these types most are available as loose media and prepacked columns for either low pressure or high performance liquid chromatography. The commercially available NTA medium (Qiagen) and Talon (Clontech) are based on Sepharose CL-6B. At the time of writing, commercial media for TACN,

TED and TREN are not available, although they can be made relatively easily using the chelator and commercially available activated media. In addition, membrane-based media can also be purchased (e.g. Sartobind IDA-Sartorius) or created via coupling of ligands to activated membranes.

Practical Considerations

The use of metal chelate chromatography should be relatively straightforward, i.e. charge with metal ions, wash, load with protein, wash and elute. However, as with most chromatographic processes there are a few points that may need close attention. In addition, the use of metal chelate chromatography has now gone beyond just the purification of proteins from crude mixtures to applications in protein folding, protein-protein interactions (footprinting) and immobilization of enzyme activities.

Protein Purification

Equipment Needs here can range from batch adsorption and elution, through very simple gravity-driven columns, to sophisticated pumping and control equipment for high performance methods. Since precise gradient mixing is not generally required, and many media present few problems with back pressure, IMAC is a relatively 'low-tech' process.

Buffers and loading conditions IMAC columns are compatible with a wide range of buffers, although those with the potential to act as chelators (e.g. citrate, Tricine) should be avoided. For the isolation of phosphoproteins on immobilized Fe^{3+} the use of phosphate buffers should be avoided. It should also be noted that phosphate buffers are not compatible with certain metals (e.g. Ca^{2+}) due to the formation of insoluble salts. The pH of the buffer will clearly be application dependent, although exposure of most columns to low pH (< 5) should be avoided since it will lead to loss of chelated metal ions due to protonation of the chelating groups. Any solutions containing imidazole should have the pH checked since imidazole can markedly alter the pH of 'buffered' solutions. Inclusion of a relatively high level of salt (e.g. 500 mM NaCl) is common practice in IMAC, serving to reduce nonspecific ionic interactions between the protein and the metal chelate complex. However, inclusion of such high levels of salt will also tend to increase nonspecific hydrophobic interactions with the column matrix. It is frequently best to ascertain the most suitable salt concentration on a case-by-case basis. The use of other chelating agents (e.g. EDTA, EGTA), often added as protease inhibitors, is also best avoided although separations

may be possible in the presence of ~ 1 mM concentrations if the load volume is relatively small compared to that of the column and/or the residence time is short. Reducing agents can also present a problem due to reduction of the metal ions, although low (10 mM) concentrations of β -mercapto ethanol may be tolerated by Ni^{2+} -NTA. Nonionic surfactants, low levels of organic solvents, 8 M urea and 6 M guanidine hydrochloride are generally compatible with IMAC. Temperature has little effect on the capacity of IMAC media.

When working with small volumes of load material or recombinant protein with a low accumulation level, the load volume/bed volume ratio becomes important. Deliberately overloading the column in such instances can improve the purity of the eluted material. In overloading the column the desired product, which binds with relatively higher affinity, will actively compete with weaker nonspecific interactions.

Certain components in common load materials from recombinant sources can introduce difficulties or potential contaminants. Insect cell media frequently contain high concentrations of histidine as a nutrient and can prevent the binding of 6His-tagged proteins being purified directly from the culture supernatant. Dialysis or dilution is required prior to loading. There is also a growing list of *Escherichia coli* proteins that regularly turn up as contaminants when purifying 6His-tagged proteins. These proteins include: chloramphenicol acetyl transferase from resistance selection; aspartate carbamoyl transferase; 30S ribosomal protein, rotamase and peptidyl prolyl *cis-trans* isomerase.

Washing Having loaded the media, in either batch or column mode, it is necessary to wash away unbound protein. This is generally achieved by washing with several bed volumes of loading buffer until the protein content of the wash material has reached an acceptable level. Low concentrations of eluting agents (e.g. imidazole) in the wash can help to improve the purity of the final product by eluting those components with relatively weak affinity. Inversely, the procedure of 'titration loading' can also be employed wherein weak binders are prevented from binding to the column by the inclusion of a low level of eluting agent in the loading buffer. Including a wash step with reduced salt can also serve to remove those potential contaminants bound to the medium via hydrophobic interactions. Proteins exhibiting such hydrophobic interaction include *E. coli*-derived proteases which, when concentrated along with target protein on the medium, can lead to severe degradation of the target. A low salt wash step can alleviate this problem.

Elution There are three potential ways of eluting protein from IMAC media:

1. Adding chelating agents that compete with the chelating ligand and the protein for metal ions.
2. Lowering the pH to protonate both the protein and the chelating groups on the chelating ligand, thus preventing metal ion chelation.
3. Introducing chelating agents that will compete with the protein for coordination to immobilized metal ion.

All three methods require further clean-up of the eluted material to remove unwanted components. Of the three methods, probably the least favourable is method 2 since this may lead to metal ion contamination of the eluted protein and retention of activity may not be compatible with low pH. Method 1 also strips the medium of metal ions, although in this instance they will be complexed with the added chelator. Method 3 is probably the most gentle form of elution. Imidazole mimics the coordination of histidine residues in the protein and can lead to effective elution when used in the tens to hundreds of millimolar range (Figure 3 shows an example purification). For phosphoproteins immobilized on Fe^{3+} it is normal to use phosphate in the elution buffer and concentrations as low as 10 mM may be effective. The minimum concentration required should be determined on a case-by-case basis and cannot be simply predicted. Even for 6His-tagged proteins the minimum concentration of imidazole required for elution can vary by an order of magnitude depending on the target protein. In some instances a sharper elution profile can be obtained by inversion of the column prior to elution. Care should be taken regarding the potential effects of imidazole on the activity of the target protein (e.g. some protein kinases will appear to be inactive until the imidazole is removed). Additionally, protein precipitation can occur during removal of > 100 mM imidazole and upon thawing frozen samples.

Protein refolding The compatibility of IMAC with 8 M urea and 6 M guanidine hydrochloride has led to its use (primarily with 6His-tagged proteins) in refolding studies on immobilized protein. The potential advantage is that the protein is anchored to a solid support, thereby reducing aggregation that may be observed in even dilute solution refolding experiments. While no generic method is available this method has been successfully used to refold a growing number of proteins. In essence washing the immobilized protein on the IMAC column replaces conventional dialysis. With the protein immobilized in the presence of a strong denaturant, the level of

Figure 3 A 6His tagged fragment encoding residues 1–117 of human mdm2 (mdm2(1–177)-6His) was expressed in *E. coli* at ~1% total cell protein. Clarified lysate (L) was loaded on to a Ni^{2+} -NTA column in lysis buffer (50 mM Tris HCl, pH 8.0, 0.5 M NaCl, 10 mM β -mercapto ethanol, 1 mM PMSF, $1 \mu\text{g mL}^{-1}$ leupeptin, $1 \mu\text{g mL}^{-1}$ aprotinin, $1 \mu\text{g mL}^{-1}$ pepstatin). After loading, the column was washed to baseline absorbance in the same buffer. Two washes were then performed: (1) 50 mM Tris HCl pH 7 and (2) as for (1) with 10 mM imidazole. Protein was then eluted by increasing the imidazole to 200 mM (3). The SDS-PAGE indicates that > 90% purity is obtained in this single chromatographic step.

denaturant is modulated in either a stepwise or gradient fashion. The refolded protein can then be eluted in a conveniently small volume.

Standard refolding protocols frequently employ dilute protein solutions and IMAC also provides a suitable method for concentrating the proteins during

such processes. However, it should be noted that not all denaturants are compatible with IMAC (e.g. 400 mM arginine employed in arginine-assisted refolding interferes with binding of 6His-tagged proteins to Ni^{2+} -NTA).

Protein–protein interactions The binding of proteins to IMAC columns can also be used to study protein–protein interactions. Having bound one protein to the column, and washed away any excess, it is possible then to expose that protein to other proteins or mixtures to detect binding. This method can be used to ‘footprint’ a specific binding interaction or to detect binding partners in a complex mixture. If weak binders are of particular interest then it is also possible to minimize post-binding wash steps and directly run the SDS-treated beads on polyacrylamide gel electrophoresis.

Conclusion

The purification of proteins on immobilized metal ions is both effective and versatile. As well as a long standing role in the isolation of proteins with naturally available histidine residues, it has now become an everyday method for the isolation of 6His-tagged recombinant proteins. Recent reviews on the separation of phosphoproteins on immobilized Fe^{3+} indicate continued interest in such applications and no doubt additional uses will be found in the future.

Introduction

Immunoaffinity chromatography is a general term that covers a range of techniques the use of which is now widespread. Often these are based upon the use of antibodies to a specific target molecule or macromolecule immobilized on some form of support (Figure 1). This is then used to separate or isolate the target molecule (or molecules of a similar structure) from a matrix in order to purify it for some subsequent purpose. Alternatively, immunoaffinity chromatography can be used to isolate antibodies by immobilizing the antigen, and indeed the first example of the use of the technique can be traced back to the pioneering work of Campbell *et al.* who, in 1951, immobilized bovine serum albumin to a derivatized cellulose in order to purify antibodies that had been raised to it (Figure 2). These immunologically-based methods include in addition immunoaffinity precipitation, immunoaffinity adsorption and immunoaffinity extraction. Indeed the use of the term ‘chromatography’ is perhaps something of a misnomer as the technique often corresponds more to the online extraction of the target molecule onto the

sorbent. Following extraction, a wash step is used to remove unwanted material followed by the recovery of the desired molecule with a strong eluent. It could thus be argued that in many applications immunoaffinity chromatography is simply immunoaffinity extraction in a column format. The term ‘immunoaffinity chromatography’ is however, widely used and understood by its practitioners.

Figure 1 Stationary phase with antibodies bound, only the antigen to which the antibodies were raised is retained. Other molecules pass through with little or no retention.

Figure 2 Stationary phase with antigen bound. Only antibodies to the antigen are retained.

Two, essentially different, types of applications of affinity chromatography can be distinguished. Thus there are those applications where isolation is with the intention of analysis (e.g. pesticides from water or drugs from blood plasma). Alternatively, immunoaffinity chromatography is used for preparative purposes and the latter is often used for the isolation of high-value proteins in the biotechnology industry.

Antibodies

The most important reagent in immunoaffinity chromatography is the antibody. These are produced by the immune system in response to foreign compounds. They are of large molecular mass (150 000–900 000). Most small molecular mass compounds such as drugs and pesticides will not provoke an immune response. The usual approach is to bind the analyte (or a structural analogue) to a carrier protein and to immunize the test species with this over a period of up to one year. Blood samples are taken and assessed for the presence of antibodies. One of the disadvantages of this type of work is that it is not certain that antibodies of suitable quality will be produced. If they are produced they are purified by techniques such as ion-exchange chromatography. Although much work is carried out on mice and rabbits, sheep are preferred as much greater volumes of antisera are produced. The antibodies produced contain a heterogeneous population of antibodies known as ‘polyclonal’. These will only be produced for the lifetime of the animal. Monoclonal antibodies contain a homogeneous population and can be

produced by the fusion of myeloma cells with the secreting cells of immunized animals to produce a hybridoma cell. In theory, these can be produced for an infinite length of time.

In the case of techniques where the antibody is immobilized to the support, both polyclonal and monoclonal antibodies can and have been used. However, with the development of methods for the production of monoclonal antibodies, these have been preferred because they offer advantages of reproducibility and a more defined specificity. In addition to the whole antibody, fragments can also be used, and these may confer advantages in terms of attaching them to the support (see below).

Immunoaffinity Supports

A considerable number of different materials have been used as supports for immunoaffinity chromatography. Traditionally, these have generally employed materials such as agarose or cellulose or synthetic polymers such as acrylamide or polymethacrylate-based materials. These provide stationary phases that can be operated under gravity flow but are less suited to systems generating high pressures or flow rates because of limited stability. The main disadvantage of such phases is that they have slow mass transfer properties and thus have a relatively low performance.

Supports based on more rigid materials such as glass and silica, or certain organic polymers such as azalactone beads or polystyrene have been produced which, because of their higher mechanical stability and efficiency, enable higher back pressures and flow rates to be used which may be important in some applications. Because of the increased performance of these materials the term ‘high performance immunoaffinity chromatography’ (HPIAC) has been coined for methods based on the use of these materials.

There are also many methods for attaching the antibody to the support. A common method is simply to covalently attach the antibody directly to the support. One method of achieving this attachment is by reacting free amino groups on the antibody with supports that are activated with e.g. *N,N'*-carbonyl diimidazole, *N*-hydroxysuccinamide, or cyanogen bromide, etc., or to supports sporting reactive epoxide or aldehyde groups. Although technically undemanding and readily achieved, such methods of attaching the antibodies to the support bring with them the problem that the random orientation of the antibodies can interfere with their subsequent ability to interact with the antigen.

Antibodies (or fragments) can also be attached to the support via rather more selective means using, e.g.

free sulfhydryls produced in the production of Fab fragments or by coupling through the carbohydrate residues of the antibody rather than amino groups. A number of sulfhydryl-reactive supports are available, e.g. maleimide, divinylsulfone, etc., for the coupling of the Fab fragments. Coupling via the carbohydrate moiety of the antibody is facilitated by mild oxidation (periodate or enzymic) to yield aldehydes. Once formed, the aldehyde can then be reacted with amine or hydrazide-derivatized supports to bond the antibody. Such immobilized antibodies are believed to provide greater accessibility for the antigen to the antibody binding site and thus provide immunoaffinity supports with higher binding capacity relative to less selective methods. However, it should be noted that this is not always the case, and some workers have compared such 'site-directed' methods with 'random coupling' using monoclonal antibodies (Mabs). These experiments used murine Mabs to either Factor IX or protein C (human plasma proteins) which were immobilized at low density to agarose matrices. The results for this study showed that the site-directed hydrazide-coupled immunosorbents had lower binding capacity for Factor IX and higher capacity for protein C than the equivalent cyanogen bromide-coupled materials.

It has also been demonstrated that the masking of the Fab regions of the antibody with a synthetic antigen prior to covalent immobilization can result in improved immunosorbent efficiency. Thus masking of a murine Mab to protein C with water-soluble adducts of poly(2-methyloxazoline) polymers and a synthetic peptide epitope was performed followed by the immobilization of the antibody complex and then the removal of the Fab-masking antigen (FMA). The procedure resulted in significantly improved antigen binding and accessibility of the Fab domain for protein C, with the best results obtained using the largest FMA employed. Whilst this work was performed on a membrane support rather than beaded material, there seems no *a priori* reason why the approach should not work in immunoaffinity chromatography as well.

There are also a variety of indirect methods of noncovalently attaching the antibody to a support. Thus the aldehyde-containing antibodies generated above can also be reacted with biotin hydrazide, which can then be attached to a streptavidin support. Alternatively, the antibody can be adsorbed onto the bacterial proteins 'protein A' or 'protein G' attached to a support. These proteins will bind to the Fc (stem) region of the antibody reasonably strongly under physiological conditions but this can be reversed by changing the pH, etc. Whilst this does not produce

particularly robust immunoaffinity supports, it can be useful in that the antibody can be replaced should the need arise, enabling the column to be regenerated. It should also be noted that protein A does not recognize all the subclasses of IgG, and has varying avidity for the IgGs of different species.

Retention and Elution in Immunoaffinity Chromatography

Retention

Retention of the compounds of interest, be they low-molecular-mass compounds or macromolecules is effected by the appropriate combination of buffer concentration and pH. Typically a pH of 7.0–8.0 would be used to promote binding to the antibody. It is also quite common to add a small percentage of sodium chloride to the buffer. Phosphate-buffered saline is the most common retention buffer quoted. In addition, in some cases, binding to the antibody depends on metal ions. For example, in the case of protein C, binding only occurs in the absence of calcium ions.

Elution

Having retained the compound or macromolecule of interest on the immobilized antibody, elution can be accomplished by a variety of methods. If the antibody is covalently bound to the support, relatively strong eluotropic conditions can be used including organic solvents such as ethanol, changes in buffer concentration and/or pH, or the use of chaotropic reagents. For speed and sharp elution profiles of the analyte/product, a rapid change in eluent composition from conditions promoting retention to those favouring elution can and are used, i.e. a simple step gradient. However, gradient elution can be used if less aggressive conditions need to be employed and the dilution of the target molecule, relative to step gradient elution, can be accommodated. A further method of elution that can be used where antibodies with relatively weak affinities are used is competitive displacement using another molecule that has an affinity for the antibody (this technique has been termed 'weak affinity chromatography'). In addition, as described below in greater detail, peptides (against which the antibodies were raised) that correspond to a particular region of the target proteins can be used to promote desorption.

Furthermore, as noted above, certain proteins binding to the antibody is metal ion dependent. Thus the protein C bound in the absence of calcium ions was eluted from the immunosorbent using a calcium chloride-containing buffer.

'Analytical' Applications of Immunoaffinity Chromatography

Immunoaffinity chromatography in essentially analytical applications can be considered under a number of headings. These include clinical analysis of endogenous macromolecules for the diagnosis and monitoring of disease, drug analysis in biological fluids (clinical, pharmaceutical and toxicological) and environmental monitoring (e.g. for pesticides in water, etc.). In such methods, a variety of analytical end points are possible ranging from the direct detection of the analyte following elution from the immunoaffinity column. Alternatively, many systems have been developed where the immunoaffinity column is placed in series with an analytical chromatography column and appropriate detector. Whatever the ultimate configuration of the system, the matrix containing the analytes passes through the immunoaffinity column which selectively extracts it allowing contaminants to pass through unretained. The analyte is then eluted from the immunoaffinity support for quantification.

Macromolecules

There are a considerable number of immunoaffinity chromatography-based methods in the literature for clinical analysis. Analytes include anti-idiotypic antibodies, fibrinogen, granulocyte colony-stimulating factor (GCSF), immunoglobulin G and E antibodies, transferrin and interferon, etc. These methods have been demonstrated to compare well with other techniques such as for example, electrophoresis or immunoassay. In such assays the columns seem to be stable up to several hundred sample applications.

Drugs

Immunoaffinity has been used for the measurement of several drugs and endogenous compounds, including anabolic steroids, betamethasone, bufuralol, clenbuterol, corticosteroids, dexamethasone, fluoroquinones, leukotrienes, LSD, morphine, *S*-phenylmercapturic acid, salbutamol, sulphathiazole, tetracyclines, and the thromboxanes TxB1 and TxB2. Matrices include blood, plasma, urine, faeces, liver, milk and honey. In the case of immunoaffinity extraction, this has been used offline (as a form of solid-phase extraction) and in HPLC column-switching mode, with the immunoaffinity column as the first column. In some instances, the immunoaffinity column was used directly on diluted urine or plasma as the only sample preparation; in others, it was used in combination with other sample pretreatment steps such as liquid-liquid extraction or protein precipitation.

Even with these most challenging samples, immunoaffinity chromatography was able to produce clean chromatographic traces.

Environmental Samples

A number of pesticides and other trace organics of environmental interest have also been determined by methods incorporating immunoaffinity chromatography. Examples include aflatoxins, algal toxins, atrazine and triazines generally, carbendazim, chlorotoluron, isoproturon and other phenylurea herbicides, mycotoxins, ochratoxin A, polyaromatic hydrocarbons, and TCDD. Matrices have included nuts, milk, shellfish, water, cereals, coffee, beer, wheat, sludge, sediment, tissue, soil, potatoes, carrots, peas, serum, and fruit juice. One of the most popular examples of the use of immunoaffinity chromatography is for the determination of pesticides in water. The antibodies bind the analyte very tightly so large volumes of water can be passed through an immunoaffinity column to facilitate trace enrichment and clean-up in one step.

Immunoaffinity chromatography has also been proposed as a simple inexpensive device for monitoring chlortoluron in water. Antibodies were bonded to a column and water passed through. Reagents to give a colour stain, the length of which would give a semiquantitative measure of pesticide concentration provided a simple rapid test.

Protein Purification by Immunoaffinity Chromatography

The purification of high-value products from complex biological matrices such as fermentation broths or extracts still represents a considerable challenge. In such preparative applications there is clearly a requirement to deal with large quantities of biological matrices (either fermentation broths or e.g. plasma after varying degrees of preliminary clean-up) compared to the analytical examples cited above. The use of larger columns also means that larger quantities of antibody are required in order to prepare sufficient immunosorbent resulting in considerable expense, which can effectively limit the range of applications. A further consequence of the high cost of the columns is the need to protect them from contamination or mechanical damage which might shorten the lifetime of the column. In addition, where the purified proteins from immunoaffinity chromatography are designed for use in the clinic it is important to ensure that the antibody does not contaminate the product due to leakage from the sorbent as it may itself produce an immune response in the patient. The cost of

the antibody has led to a considerable amount of work aimed at optimizing the capacity of the sorbents, as well as the optimization of flow rates, pressure limits and mechanical stability. It seems to be generally accepted that the typical operational life of such a column is about fifty uses without significant loss of purification capacity, depending upon matrix and process conditions.

An illustrative example of the use of immunoaffinity chromatography for the purification of a protein is provided by studies on protein C, a vitamin K-dependent glycoprotein. This protein has a molecular weight of 62 000 Da, comprising a light chain of 21 000 Da and a heavy chain of 41 000 Da and contains some 23% as carbohydrate. Protein C has potent anticoagulant properties and it is envisaged that there may be potential for its use therapeutically for patients with protein C deficiency, abnormal clotting problems or in victims of heart attacks, etc. In this study a murine monoclonal antibody (Mab 8861) to human protein C was bonded to a variety of support materials and their comparative performance assessed. Columns prepared with these materials were equilibrated with an adsorption/wash buffer (consisting of 0.02 mol L^{-1} sodium citrate, 0.08 mol L^{-1} sodium chloride) at a pH of 6.0 (chosen to increase the stability of the load material). The sample containing protein C was then loaded on to the column which was then left for 30 min to ensure sufficient time for the protein to interact with the antibody. The column was then washed for a further 30–40 min (4–5 column volumes) after which the elution solvent (0.1 mol L^{-1} sodium carbonate, 0.15 mol L^{-1} sodium chloride pH 10) was applied to the column to recover the protein C. The eluent containing the protein C was then immediately taken to pH 7.5 with HCl. However, as described above the binding of protein C can also be dependent on the absence of calcium ions, and in an alternative protocol, using the murine antibody 7D7B10-Mab to human protein C (bound to either agarose or cellulose) this property was exploited. Thus feedstock from the recombinant protein (pre-centrifuged transgenic pig milk whey containing 50 mmol L^{-1} EDTA) was diluted with buffer (1.0 mol L^{-1} sodium chloride, 0.05 mol L^{-1} Tris, 0.025 mol L^{-1} EDTA at pH 7.0) (3 parts buffer to 1 part whey). After centrifugation, the sample was applied to the immunosorbent, and the columns then washed with 18 volumes of buffer. Elution was accomplished with the same buffer with the addition of 25 mmol L^{-1} calcium chloride. Following elution the columns were then regenerated with successive washes of 4 mol L^{-1} sodium chloride, 2 mol L^{-1} sodium thiocyanate and then the application buffer (with 5 mmol L^{-1} EDTA).

Obviously one problem that afflicts all immunoaffinity-based methods is that an antibody to the target protein must first be raised, which may be difficult if the target protein is not available in sufficient quantity or purity. It has now been demonstrated that, for example, peptides to the C-terminal regions of chimeric α -amylase, recombinant CD2 and the insulin β -chain can be used to obtain antibodies. These rabbit antibodies had sufficient affinities to the target proteins to be suitable for use on immunosorbents. The peptide to which the antibody has been raised can then be used as a mobile-phase additive in the eluent in order to displace the target protein from the antibody. Thus, when processed fermentation broths containing the target protein mentioned above were applied to the column they could be recovered either using non-specific eluents (e.g. 2.5 mol L^{-1} sodium thiocyanate, 5 mmol L^{-1} calcium chloride, pH 5.0 for the amylase), or by eluents containing the appropriate peptide in a sodium acetate (50 mmol L^{-1})–calcium chloride (5 mmol L^{-1}) buffer at pH 5.0. For the amylase example, concentrations of the peptide in the eluent of 0.153 or 0.48 mg mL^{-1} produced similar elution profiles, with recoveries of 50–60% of the adsorbed protein (similar to the recoveries with the nonspecific eluent). To regenerate the immunoaffinity column the peptide was then eluted with 0.1 mol L^{-1} HCl. This process of protein purification is interesting as it avoids the use of chaotropic reagents, and also resulted in high-purity products. Post-elution from the column, the proteins and eluting peptides could be separated by ultrafiltration or gel permeation chromatography.

As these examples show, immunoaffinity chromatography for protein purification is a well established and effective method for obtaining high-value proteins, with a continuing high level of innovation.

Conclusions

Immunoaffinity chromatography is a widely used, and useful, family of techniques for the isolation or analysis of both macromolecules and low-molecular-mass compounds for either preparative or analytical purposes. Continuing advances in the production of antibodies and immunoaffinity phases by the use of improved supports and coupling chemistries will result in higher capacities and longer-lived materials. These advances will undoubtedly result in the increased use of immunoaffinity methods in analytical chemistry and in biotechnological applications.

Introduction

Molecular imprinting is now recognized as one of the most rapid and powerful methods for creating tailor-made synthetic receptors with strong, yet selective, affinities for a diverse selection of analytes. The imprinting of small organic compounds, metal ions and peptides is well developed and almost routine, and the imprinting of much larger analytes, such as proteins and cells, has also now been demonstrated. The impressive molecular recognition characteristics of molecularly imprinted materials, allied to their highly robust physical nature, makes them ideally suited for numerous applications in affinity separation. This article will outline the general principles behind molecular imprinting and the generic approaches to the preparation of imprinted materials. Particular emphasis will be placed on their role as affinity materials in separation science.

The Imprinting Principle

Molecular imprinting has been demonstrated in silica and in synthetic organic polymers, but it is organic polymers that have found the most favour and indeed probably have the most to offer to the affinity separation area. The rest of this article will therefore deal exclusively with molecular imprinting in the latter medium.

The technique of molecular imprinting in organic polymers is a polymerization process in which a rigid, and insoluble, macroporous polymer network is formed around an analyte (template) of interest (**Figure 1**). In a typical imprinting experiment the analyte is initially allowed to form, in solution, an assembly with one or more functional monomers, which interact with the analyte via either covalent or non-covalent bonds. Once the assembly has been generated, copolymerization with an excess of cross-linking monomer (usually >50 mol%) is initiated, and the insoluble polymeric product phase separates from solution as the polymerization proceeds. The analyte functions as a template during the

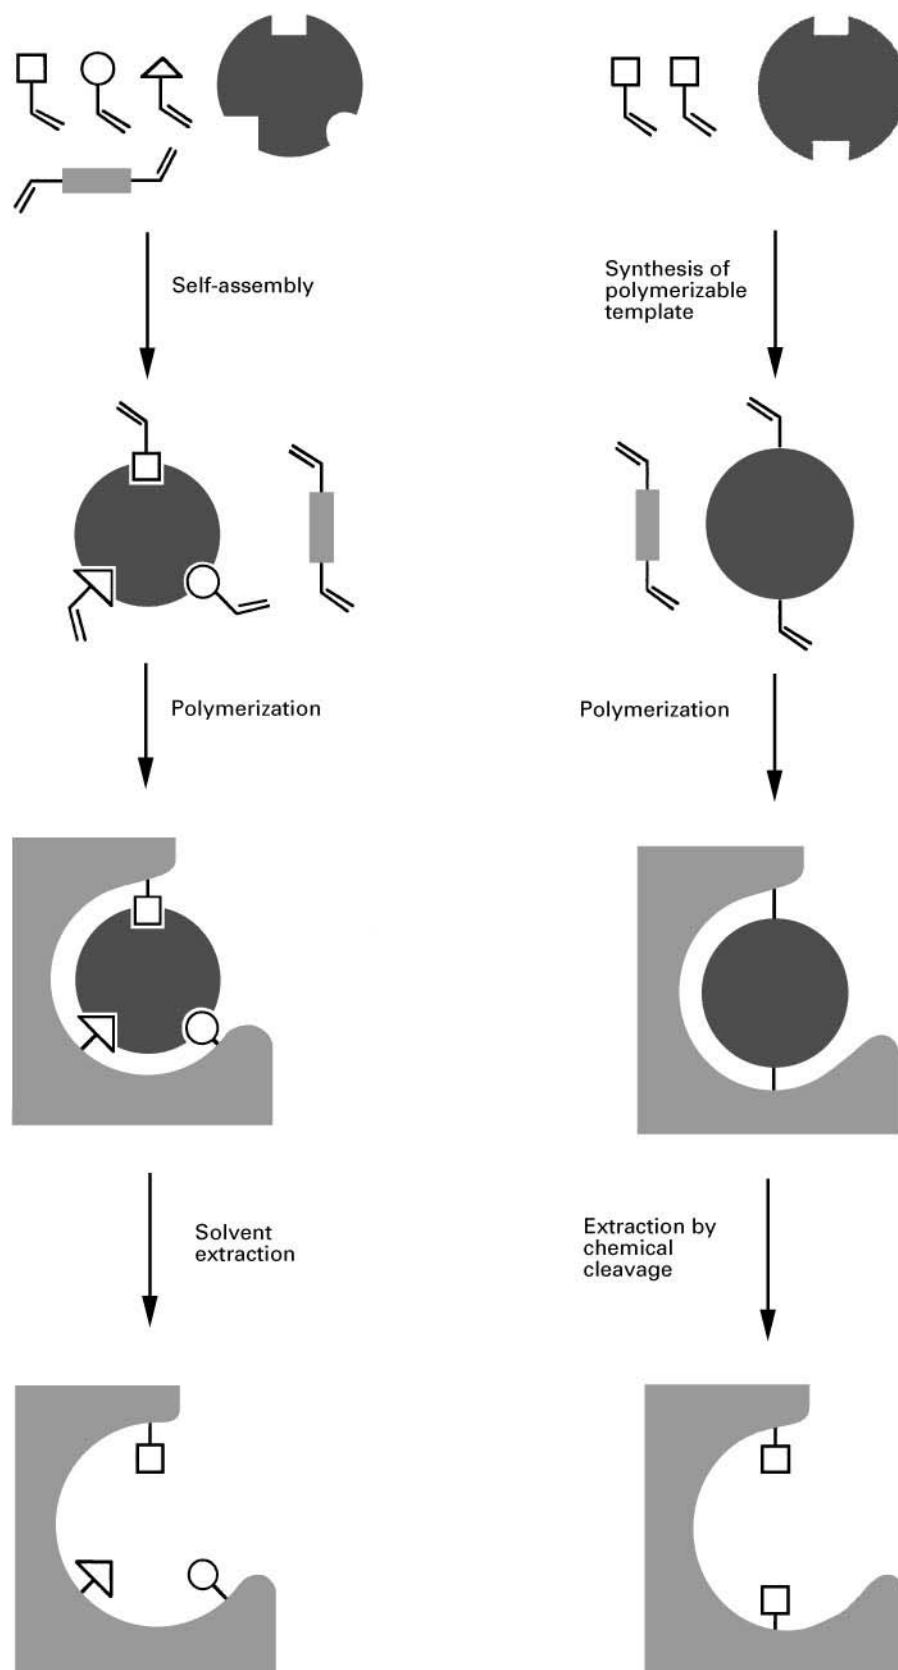

Figure 1 Schematic representation of the molecular imprinting principle. Non-covalent approach (left) and covalent approach (right).

polymerization process, controlling the chemical functionality of the polymer network which forms around it, and since the polymer network is macroporous and the interactions between the analyte and the polymer are quite labile, the analyte can subsequently be extracted from the network via either a simple solvent washing step or by relatively mild chemical treatment. The extraction process reveals binding sites within the polymer network which are complementary to the analyte in terms of their size, shape and functionality, and the polymer can therefore specifically rebind the analyte in these cavities. It is this ability to specifically rebind an analyte which can be taken advantage of in affinity separations.

Numerous analytes have now been successfully imprinted, the majority of which are small, organic compounds, such as drugs, amino acids, sugars and pesticides (Table 1). Metal ions and larger organic compounds (e.g. peptides) have also been imprinted. Although the imprinting of much larger analytes, for example proteins and cells, is in principle and in practice somewhat more difficult to achieve, this has now been demonstrated also.

As mentioned already, there are two distinct imprinting approaches that one can follow. The first is the so-called covalent approach (pre-organized approach) in which the interactions between the analyte and the functional monomers in the pre-polymerization assembly are covalent in nature (this classification generally also includes metal-coordinated analytes). Extraction of the analyte from the network requires these covalent bonds to be cleaved, but they are reformed upon subsequent analyte rebinding. In contrast, non-covalent bonds (e.g. hydrogen bonding, ion pairs and π - π interactions) exist between the analyte and the functional monomers in the pre-polymerization assembly in the non-covalent (self-

assembly) approach. Rebinding of the analyte to the polymer is also non-covalent in nature.

Both imprinting approaches have their own merits and drawbacks, but what can be said in general is that the covalent approach yields binding sites that are better defined. However, it does require chemical derivatization of the analyte prior to polymerization, which is not always easy or practical. The non-covalent method, on the other hand, requires no chemical derivatization step, and is therefore much more general in nature and applicable to a considerably wider range of analytes. Rebinding kinetics are also much more favourable. Indeed, because of its inherent simplicity, the non-covalent approach tends to be the method of choice, although the overall quality of the binding sites tends to be somewhat poorer.

As for the binding sites themselves, the strength and the selectivity of analyte rebinding has been shown in some cases to be on a par with those of natural receptors such as antibodies. This is quite remarkable in itself. In a typical imprinted polymer, however, there is usually a variety of binding sites with different affinities for the analyte, and it is only those sites with the strongest affinities which are comparable to the binding affinities of antibodies. In analogy with antibody terminology, such polymers are usually termed polyclonal to describe their heterogeneous populations of binding sites. There is, needless to say, considerable effort being made to prepare imprinted polymers with homogeneous binding sites, i.e. monoclonal materials.

Besides their impressive molecular recognition properties, molecularly imprinted polymers have several other attractive features. They are exceedingly robust, and can be utilized under conditions which would be disastrous for enzymes or antibodies. They are stable at elevated temperatures and pressures, they are resistant to many chemical environments and can be used in both aqueous and non-aqueous media. Furthermore they are of low cost, have good shelf-lives and can be re-used time and time again without significant detriment to their properties.

In terms of potential applications for imprinted polymers, several avenues are being explored. Imprinted polymers are showing promise as molecular recognition elements in *biomimetic sensors*, as *antibody binding mimics* ('plastic antibodies'), as *catalysts* ('plastic enzymes') and in the *screening of chemical libraries*, but it is in the *affinity separation* area where they are attracting the greatest attention. Indeed, they have already shown their value in chromatography, solid-phase extraction, capillary electrophoresis and membrane separations. Before moving on to consider these applications in greater

Table 1 A selection of analytes that have been imprinted

<i>Analytes imprinted</i>	<i>Examples</i>
Drugs	Propanolol, diazepam, pentamidine, nicotine
Hormones	Enkephalin
Steroids	Steroidal ketones, cholesterol, testosterone
Amino acids	Various free and derivatized amino acids
Peptides	Various small peptides
Carbohydrates	Various sugar derivatives
Proteins	RNase A, transferrin, haemoglobin
Co-enzymes	Pyridoxal derivative
Nucleotides	NAD ⁺
Nucleotide bases	9-Ethyladenine
Pesticides	2,4-D, atrazine, triazine
Dyes	Rhodanile blue, Safranin O
Metal ions	Ca ²⁺ , Cu ²⁺ , Hg ²⁺ , Eu ³⁺
Bacteria	<i>Listeria monocytogenes</i>

detail, the chemical constitution of molecularly imprinted polymers and general methods for their preparation will be briefly described.

The Preparation of Molecularly Imprinted Polymers

Success in the preparation and application of molecularly imprinted polymers relies upon a good understanding of both the principles and practicalities behind the imprinting process. Although a complete, in-depth guide to the preparation of good quality imprints for all analytes is far beyond the scope of this article, there are some general guidelines which provide a good basis for success. The generalities are covered here. The specific details can be found elsewhere.

Nature of the Analyte

The majority of analytes imprinted to date have been low molecular weight organic compounds of molecular mass 200–300 Da, but with appropriate modification of the imprinting conditions much larger analytes can also be imprinted. Various chemical and physical properties of the analyte are of considerable importance; besides having a suitable chemical handle for interaction with a functional monomer, an analyte must be compatible with the functional monomers and crosslinkers used, it must be soluble in the solvent(s) used for imprinting, and it must be stable and inert under the polymerization conditions employed.

Functional Monomers

Functional monomers are selected based on their ability to bind reversibly, via either covalent or non-covalent bonds, to the analyte. In covalent imprinting approaches, the covalent bonds linking the functional monomers to the analyte need to be reasonably labile to allow removal of the analyte from the polymer matrix under relatively mild conditions. This requirement is somewhat limiting, and only metal-chelates, boronic acid esters, disulfides and Schiff bases have been developed to any great extent. The non-covalent approach is much less restricting in this respect, and numerous vinyl-based monomers have been successfully employed (Table 2).

In non-covalent imprinting protocols, the analyte–functional monomer assembly is dynamic in that the functional monomers exist in both the free and the complexed state, and indeed are free to move from one state to another. To push the equilibrium towards assembly formation, it is not unusual to use an excess of functional monomer in the polymerization mixture (typically two-fold or greater). This

does have the side effect of increasing the level of non-specific rebinding of the analyte to the polymer, but at the same time it increases the number of good binding sites, so it is a compromise.

Cross-linking Monomers

Copolymerization of the functional monomers with an excess of cross linking monomer (usually >50 mol%) yields an insoluble polymer matrix which phase separates from solution as the polymerization proceeds. High ratios of crosslinking monomers are generally required to give the polymer matrix the rigidity necessary to retain the integrity of the binding sites. Usually analyte rebinding is enhanced considerably as the crosslinking ratio is increased up to 80 or 90 mol%. The improvements in recognition thereafter are much less spectacular. Many different crosslinking monomers have been used, including some which act simultaneously as functional monomers, but the three which have found the most favour are ethyleneglycol dimethacrylate (EGDMA), divinylbenzene (DVB) and trimethylolpropane trimethacrylate (TRIM) (Table 3).

Solvents

The solvent, besides acting as the medium in which the polymerization is performed, has an important secondary role as a porogen. It controls the porous structure of the polymer matrix to a large extent, and a good porogen is essential if one wants the porous structure in the polymer to be well developed. Sometimes, however, a good porogenic solvent can be a bad solvent for the analyte, so once again a compromise is sometimes required. Common imprinting solvents include toluene, chloroform and acetonitrile.

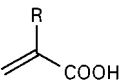

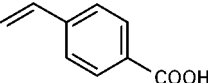

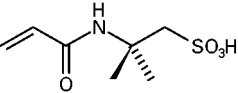

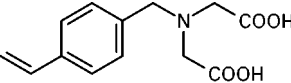

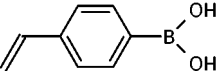

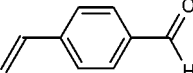

In non-covalent imprinting, there is one further solvent effect which is of great importance. Polar solvents destabilize the analyte–functional monomer assembly and it is therefore better to use non-polar solvents, whenever possible, to maximize the concentration of the assembly in the pre-polymerization mixture. The same argument applies for analyte rebinding. In spite of this, non-covalent imprints have in some cases still shown good recognition properties in aqueous buffers, which are of course highly polar.

One final point of note, which applies to both covalent and non-covalent approaches, is that the best recognition is generally observed when the solvent used for both the polymerization and analyte rebinding is the same.

Initiators and Polymerization Conditions

Classical free radical initiators such as 2,2'-azobisisobutyronitrile (AIBN) are commonly used to

Table 2 A selection of functional monomers commonly used in molecular imprinting

Functional monomer(s)	Structure	Approach
Acrylic acids	 $R = H, CH_3, CF_3 \text{ etc.}$	Non-covalent
Vinylpyridines		Non-covalent
Acrylamide		Non-covalent
Vinylbenzoic acids		Non-covalent
Acrylamido-sulfonic acids		Non-covalent
Vinyl-iminoacetic acids		Metal coordination
Vinylboronic acids (for boronate esters)		Covalent
Vinylbenzaldehydes (for Schiff bases)		Covalent

initiate the polymerization under either thermal or photochemical conditions. Thermal conditions may be preferred in some cases due to limited analyte solubility at lower temperatures, but photochemical initiation at these lower temperatures has certainly been shown to give better results in non-covalent imprinting.

Physical Form of Imprinted Polymers

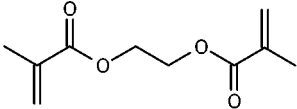

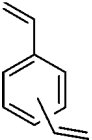

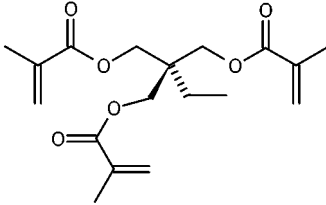

Molecularly imprinted polymers can be prepared in a variety of forms to suit the final application desired. The most common, and indeed the crudest, method for preparing molecularly imprinted polymers is via solution polymerization followed by mechanical or manual grinding of the monolithic block generated, to give small, molecularly imprinted particles. If required, sizing of the particles through sieving and/or sedimentation can then be performed. Besides being

time consuming and wasteful, this method produces particles of irregular shape which are not ideal for chromatographic applications. The grinding process may also destroy a few of the binding sites. Improved polymerization methods which obviate the need for grinding are therefore being investigated.

One seemingly general method which has been developed, and which overcomes the grinding problem completely, involves the suspension polymerization of imprinting mixtures in liquid perfluorocarbon continuous phases. Spherical beads of controlled, regular diameters (down to ca. 5 μm) can be prepared reproducibly by this technique, and are isolated simply by filtration. In the same way, imprinted beads can also be obtained via emulsion, seeded emulsion or precipitation polymerization methodologies.

For chromatographic applications, another solution to the grinding problem is to perform the polymerization directly inside the chromatographic column,

Table 3 Crosslinkers commonly used in molecular imprinting

Cross-linker	Structure
Ethyleneglycol dimethacrylate (EGDMA)	
Divinylbenzene (DVB)	 Usually a mixture of isomers
Trimethylolpropane trimethacrylate (TRIM)	

i.e. *in-situ* polymerization. This approach is particularly attractive for capillary electrophoresis applications, where filling of the capillary can often be problematic.

One final format, which is finding increasing interest, involves imprinted membranes. Generally they are composed either of crosslinked polymers which have been prepared in the standard way, or of linear polymers which have been precipitated in the presence of the analyte. They can be either free-standing or supported.

Applications in Separation Technology

As mentioned earlier, the application of imprinted polymers that has been the most extensively explored

is separation and isolation. *Chiral separations* have been a major area of investigation, and indeed molecularly imprinted materials have been employed as chiral matrices in several different separation techniques. A characteristic of imprinted chiral separation matrices is the pre-determined migration or elution order of the enantiomers, which depends only on which enantiomer is used as the template molecule. For instance, when the *R*-enantiomer is used as the template, it will be retained more by the polymer than the *S*-enantiomer, and vice versa (Figure 2). The discrimination of enantiomers is often very efficient with molecularly imprinted materials. Highly selective, chirally discriminating recognition sites have been prepared using covalent or non-covalent imprinting protocols, and large separation factors between the enantiomers have been recorded.

For analytes containing two chiral centres, all four stereoisomers may be selectively recognized by the imprinted materials. Thus, for a polymer imprinted against the dipeptide Ac-L-Phe-L-Trp-OMe, the LL-form can be selectively distinguished from the DD-, the DL- and the LD-isomers. In systems where more than two chiral centres are involved, such as carbohydrates, these properties of molecularly imprinted materials become even more significant. For example, in a study where polymers were imprinted against a glucose derivative, very high selectivities between the various stereoisomers and anomers were recorded.

Apart from the separation of enantiomers, imprinted polymers are also very useful for the separation of other compounds with closely related structures. An overview of the different separation techniques in which molecularly imprinted polymers have been employed is given below.

Liquid Chromatography

The use of imprinted polymers as stationary phases for HPLC is by far the most studied application. This

Figure 2 Typical chromatograms of an enantiomeric mixture using a polymer imprinted with the L-enantiomer, a polymer imprinted with the D-enantiomer and a non-imprinted polymer as column packing material.

is partly for historical reasons, because liquid chromatography is a convenient method for assessing the quality of an imprint, particularly during the optimization of an imprinting protocol.

Most research has concentrated on chiral resolution, and molecularly imprinted chiral stationary phases have been prepared for a wide range of compounds. Many of the early investigations employed amino acid derivatives as model substances. In recent years, however, a great deal of emphasis has also been put on the chiral discrimination of drug compounds. Several studies involving the separation of physiologically active compounds, e.g. naproxen (a non-steroidal anti-inflammatory drug), ephedrine (an adrenergic agent) and timolol (a β -adrenergic antagonist) have been described. Typically, separation factors of between 1.5 and 5 are obtained with imprinted polymers, which is relatively high when compared with other chiral stationary phases. In consequence, excellent separations should be possible to achieve in theory, but in practice several factors often lead to rather modest results, especially in terms of resolution. The heterogeneity in the binding site affinities and accessibilities in non-covalently imprinted polymers often leads to band broadening and peak tailing, and thus to a poor column efficiency. Even for non-retained compounds, low plate numbers ($2000\text{--}5000\text{ m}^{-1}$) are usually obtained. One factor which has a deleterious effect on the separation is the unfavourable shape and size distribution of particles, which leads to poor flow characteristics and low functional capacities. A good strategy to improve the performance of imprinted stationary phases should therefore take into account the following aspects:

- *Optimization of particle size and shape.* This can be achieved by using suspension polymerization procedures for instance, which can generate uniformly sized spherical beads of controlled dimension.
- *Optimization of the column packing.*
- *Optimization of the mobile phase.* In many cases, the addition of competitors can improve peak shapes, and carefully designed gradient elution protocols can minimize tailing, especially of the more retained peak.
- *Increasing the capacity of the imprinted stationary phase.* This can be realized by optimizing the polymer recipe. It has been shown that substituting trimethylolpropane trimethacrylate for ethylene-glycol dimethacrylate as the crosslinker leads to higher load capacities, since a lower degree of crosslinking is necessary and more functional monomer can be accommodated in the polymer,

i.e. the number of theoretical binding sites is increased.

By these means, improved separation and resolution can already be expected. However, the most important issue is certainly the binding site heterogeneity, which is undesirable and has to be addressed. In order to obtain a more homogeneous population of binding sites in an imprinted polymer, the pre-polymerization complex between the template and the functional monomers has to be stabilized. Certainly, covalent bonds should give the best results in this respect, but even stronger or multiple non-covalent interactions between monomer and template will afford a more stable complex. For example, acrylamide or trifluoromethylacrylic acid can in some cases be substituted for methacrylic acid, resulting in a considerably improved separation which can be attributed to the stronger noncovalent bonds formed by these monomers as compared to methacrylic acid.

Thin Layer Chromatography

Finely ground imprinted polymer coated on to an inert support has been suggested for use in chiral TLC. Although only a limited amount of work has been done in this area, it has been shown that the racemates of a number of amino acids can be resolved. Problems were encountered due to band broadening, which led to the formation of zones rather than small spots or thin bands. This in turn led to band overlap and poor resolution, and measurements of R_f values were also made more difficult. However, this method may nevertheless be attractive for the determination of the enantiomeric purity of compounds such as a chiral drugs, owing to its simplicity, its speed and the possibility of running multiple parallel samples. Optimization of particle shape, size and porosity, similarly HPLC, will probably result in considerably improved shape of the bands.

Capillary Electrophoresis

The feasibility of using imprinted polymers as selective matrices for affinity capillary electrophoresis and capillary electrochromatography has been demonstrated. Owing to the difficulty in packing ground polymer particles or polymer beads into microbore capillaries, an *in-situ* polymerization seems better suited for this application. Imprinted capillaries have been prepared by *in-situ* synthesis of a macroporous polymer monolith within the capillary, which can be covalently attached to the capillary wall. Ideally, the polymerization is carried out in such a way that

the capillary is not completely filled with polymer and an axial flow-pore is obtained, which allows the solvent to be exchanged easily. Entrapping imprinted polymer particles in a polyacrylamide gel formed *in-situ* in the capillary has been suggested as an alternative way of preparing imprinted capillaries. However, this approach seems to be somewhat less practical since the solvent cannot be exchanged easily and because the lifetime of such capillaries may be rather short due to problems with air bubble formation during operation.

Enantioselective imprinted columns for capillary electrochromatography could be very useful, especially because considerably higher efficiencies can be obtained ($>100\,000$ plates m^{-1}) than with HPLC columns. Chiral separations of drugs such as the β -adrenergic antagonist propranolol have been achieved within 2 min, and an enantiomeric mixture containing as little as 1% *S*-enantiomer could be resolved. Since imprinted capillaries can be prepared quickly and easily, and are normally very stable in use over a period of several months, this represents a highly promising development for analytical chiral separations.

Membrane-based Separation

Chromatographic separation techniques are well established and widely used, however they do have some limitations, especially in the scale-up of separation processes. For larger-scale separations, they are therefore often replaced by membrane-based techniques, since membranes can be used in continuous mode unlike the batch-wise operation in chromatography.

Polymeric membranes can be made specific for certain target molecules by molecular imprinting. Imprinted membranes have been prepared in different ways; they can be cast directly as a thin layer on a flat surface or between two surfaces, and may or may not contain a stabilizing matrix. Alternatively they can be prepared by a phase inversion precipitation technique. Although imprinted membranes have great potential for applications in separation, especially chiral separation (enantiomeric polishing), they have until now merely been used in model studies and as recognition elements in biomimetic sensors. As an example, molecularly imprinted polymer membranes have been shown to be capable of distinguishing between enantiomers or otherwise closely related molecules. Usually, such membranes facilitate the diffusion of the compound which was imprinted relative to other closely related molecules. Thus, a membrane imprinted with 9-ethyladenine showed faster transport of adenosine

than of guanosine. In other applications, selective retention by the membrane of the compound which was imprinted has been observed. For example, chiral discrimination was possible for D,L-phenylalanine, with the passage of the imprinted enantiomer being retarded.

Solid-phase Extraction

Owing to their ability to bind antigens specifically, antibodies have been used in immunoaffinity chromatography and immunoextraction protocols specifically to enrich an analyte prior to its quantification in, for example, medical, food and environmental analysis. Furthermore, it has been demonstrated that the natural receptors can be successfully replaced by imprinted polymers. The use of imprinted polymers for sample concentration and clean-up by solid-phase extraction is attractive due to their high specificity and stability, and also their compatibility with both aqueous and organic solvents. Often the work-up of samples in routine analysis involves a solvent extraction step or a solid-phase extraction step with a more general adsorbent, e.g. an ion exchange or hydrophobic resin. This could be replaced by solid-phase extraction with an imprinted polymer. The advantages are an increased selectivity of the extraction step, and a reduced solvent consumption.

The applicability of this method for analysis has been demonstrated on a number of model compounds such as drugs and herbicides, which can be selectively extracted even from complex samples like beef liver extract, blood serum, urine and bile. For example, the analgesic drug sameridine could be extracted from blood plasma at a concentration of 20 nmol L^{-1} , and subsequently quantified by GC. In this way, much cleaner chromatograms were obtained as compared to the standard liquid-liquid extraction method (Figure 3), since fewer contaminants were co-extracted with sameridine by the imprinted polymer-based method.

In analytical applications, problems may be encountered due to small amounts of template remaining in the polymer even after very thorough solvent extraction. This may falsify the results of the analyte quantification following the solid-phase extraction step if traces of the template are released into the sample. A possible solution to this problem is to use, as the template, a molecule with a structure very closely related to the target analyte, rather than the analyte itself. In such a case, the polymer may still bind the target analyte specifically, whereas traces of template liberated during the extraction procedure can be separated from the target analyte upon sub-

Figure 3 GC traces of human plasma samples spiked with sameridine and an internal standard, and subjected to (a) solid-phase extraction with an imprinted polymer, and (b) standard liquid-liquid extraction. The peaks are the template molecule (1) (a close structural analogue of sameridine), the analyte sameridine (2) and the internal standard (3). (Adapted with permission from *Chromatographia* (1997) 46, 57).

sequent analysis. This approach was demonstrated very nicely for the sameridine case described above, where a close structural analogue of sameridine was imprinted. The polymer displayed a high affinity for sameridine as well as for the analogue, but the two compounds could be readily separated by GC and the sameridine quantified.

Apart from analytical applications, imprinted polymers may also be used for preparative separations, e.g. for product recovery during chemical and enzymatic syntheses, or from fermentation broths or production waste streams. However, for the time being at least, the low binding capacity of imprinted polymers might limit these applications.

It should also be mentioned here that imprinted polymer particles or beads can be made magnetic, which can be advantageous in both analytical and preparative applications since it enables easy removal of the polymer from the extracted medium.

Conclusions

In summary, molecularly imprinted polymers have much to offer to the area of affinity separation. Their highly attractive physico-chemical properties allied to their impressive molecular recognition properties make them particularly well suited for application in a number of important areas, including chromatography, solid-phase extraction, capillary electrophoresis and membrane separations. The period of hitherto unknown expansion, which the molecular imprinting field is currently enjoying, bodes well for the future, and molecularly imprinted polymers will surely play an ever increasing part in affinity separation as the molecular imprinting field matures further.

Introduction

For years, the structure, function and dynamics of proteins have intrigued biochemists and chemists and inspired the design of targeted low molecular weight drugs. Today, as biotechnology progresses, proteins are themselves being used in the treatment of several diseases. Almost every gene can now be cloned and its protein product produced in any expression system depending on the desired folding, stability, post-translational modification, cost of production and ease of recovery. An increase in the isolation of large volumes of recombinant proteins such as antibodies, antivirals, cytokines, enzymes, clotting factors and vaccines for therapeutic, diagnostic and research purposes has made efficient protein purification the most important step in the recovery of efficacious and fully active biopharmaceuticals.

All steps in the production of biopharmaceuticals need to be compliant with the safety guidelines laid out by regulatory authorities such as the US Food and Drug Administration and the equivalent European authority. The final product should be a 'well characterized biologic' with defined major impurities, if any, very low levels of DNA and viruses (less than 10 pg per dose), pyrogens (less than 300 endotoxin units per dose) and leachates from the separation matrices. **Table 1** highlights some of the quality control requirements imposed by the regulatory authorities on proteins used for clinical applications. Commonly purified end products are mixtures of isoforms of proteins with variations in post-translational modifications such as glycosylation, oxidation, end terminal alterations, misfolding, incorrect disulfide bridging and nicked or truncated variants. Thus, techniques such as high performance liquid chromatography (HPLC), peptide mapping, capillary electrophoresis, isoelectric focusing, circular dichroism and mass spectrometry are also gaining an impetus in thorough characterization of the potency, purity and safety of protein drugs.

The increasing demand for peptides, nucleotides, low molecular weight synthetic molecules and biomimetic ligands for protein purification has inspired chemists to generate focused and general combinatorial libraries of diverse compounds. Rational ligand

or drug design can provide directionality and help increase the possibility of success, even with a small library of compounds. In this article we have tried to give the reader an overview about sophisticated technologies and alternatives to peptides and nucleotides for protein purification and the art of ligand design for focused combinatorial synthesis.

Affinity Chromatography

The choice of purification strategy is largely contingent on its performance and economics, which is related to the effectiveness of the separation strategy employed and its robustness. Conventional purification techniques based on precipitation with salts, temperature, pH and high molecular weight polymers are now being substituted by highly selective and sophisticated strategies based on affinity chromatography. This highly selective technique simulates natural processes such as biorecognition. Molecular recognition encompasses interactions such as those between enzyme and substrates, antigens and antibodies, ligands and receptors, DNA and protein interactions, viral proteins and cell surface glycoproteins, hormones and transmitters that generate a cascade of events to carry out important biological activities. Exploitation of this affinity for interaction between target proteins and their complementary ligands or binding partners is the essence of all affinity techniques. The concept can be traced back to 1910 when Starkenstein first reported the isolation of α -amylase by adsorption onto insoluble starch, and was subsequently followed by several remarkable examples. Only in the second half of the 20th century did the use of the technique gain momentum and the technique was termed affinity chromatography in 1968 by Cuatrecasas. **Table 2** outlines the historical perspectives in the development of affinity chromatography. Ever since, techniques in affinity chromatography

1990	<i>De novo</i> ligand design

have been considerably refined for compliance with present-day strict quality control demands such as end product purity, safety, potency and stability. The choice of a stable and efficient solid support, activation and coupling chemistry and selection of a ligand have been investigated in detail since they contribute to efficient recoveries of the target protein.

The most commonly employed adsorbents in affinity chromatography are based on biomolecules such as monoclonal antibodies that offer selectivity and specificity. However, these adsorbents, besides being expensive, are prone to chemical and biological degradation, and themselves need purification prior to immobilization on a solid support and may have issues such as viruses and nucleic acids associated with them. Although biologicals have high selectivity, they have low capacities, a limited life cycle and a low scale-up potential. To counteract these problems, more durable and controllable peptides, peptidomimetics and synthetic ligands were introduced.

Peptide-based Ligands

In the last few years, peptide libraries have been a major area of development for the selection of biologically active peptides. These libraries offer the opportunity to study interactions between proteins and their natural ligand and are being used as potential drugs, antimicrobials and enzyme inhibitors, as bioactive peptides and as ligands for protein purification. Peptide libraries can be generated either by phage display or synthetic solid- or solution-phase chemical approaches. One of the most widespread and commonly used peptide-based technologies, phage display was conceived in 1985 by Smith and has been revolutionary in the synthesis, diversity and application of random peptide libraries in the search for novel protein-binding ligands for purification, structural and functional studies.

Random peptides are displayed on the surface of a filamentous bacteriophage (M13 or related bacteriophages) by fusion of the desired DNA sequence with either the minor (gIII) or major (gVIII) coat proteins of the bacteriophage. Multiple copies (five to thousands) of the peptide are then expressed on the bacteriophage surface owing to the presence of several copies of the coat proteins. Preparation of a large number of random oligonucleotides helps generate a combinatorial library of several millions of peptides. Selection of the phage particles expressing the peptide sequence with the desired activity and selectivity is performed through a process termed 'bio-panning'. The desired receptor for the peptides is immobilized on a solid support and the peptide-phage particles are loaded. The peptide-phage assemblies that do not bind wash off and the ones bound are eluted and amplified in *Escherichia coli*. The entire process is repeated 2–3 times to wash away any nonspecifically or weakly bound assemblies. The sequence of the selected peptide is determined by sequencing the coding region of the viral DNA.

The criteria for evaluation of peptide libraries includes generation of all possible combinations (millions) and numbers of peptide sequences to give the maximum probability of finding success. This aspect highlights the importance of rapid and efficient high-throughput screening for analysis of thousands or hundreds of millions of peptide candidates. The length of the sequences should be such that they include equimolar amounts of the tetramers and hexamers and the library should incorporate natural L-amino acids, their D-counterparts and unnatural amino acids.

In comparison with synthetic peptide synthesis, phage display is less labour-intensive and does not involve the painstaking synthesis of limited numbers of peptides. The peptide libraries can help localize

epitopes on the surfaces of antibodies (monoclonal or polyclonal), act as enzyme inhibitors, mimic cytokines, and DNA binding proteins may be used in the design of novel ligands for peptide receptors. The ability to identify regions in a protein that interact with certain peptides without dependence on structural data and other pre-existing data is remarkable. The opportunities in drug and ligand discovery are substantiated by a number of remarkable applications in the literature.

Oligonucleotide-based Ligands

Oligonucleotide (DNA or RNA)-based combinatorial chemistry has been exploited in a technology called SELEX (systemic evolution of ligand by exponential enrichment) to identify and isolate high affinity ligands directed for proteins, nucleic acids and low molecular weight targets such as peptides. The K_d values for such types of ligands are between 10^{-9} and 10^{-12} mol L⁻¹ for proteins and between 10^{-6} and 10^{-9} mol L⁻¹ for low molecular weight targets. The methodology involves random condensation of a mixture of activated monomers for generation of a combinatorial array of nucleic acid sequences that are assessed for binding towards any target (protein, nucleic acid, peptide or low molecular weight compound). The sequences are amplified by polymerase chain reaction, and the ones that show positive activity are selected and reamplified. The numbers of sequences that can be generated by commercially available synthesizers have been reported to be 10^{14} – 10^{15} in literature. The multiple rounds of selection exponentially enrich the group of oligonucleotide ligands with high affinity for the target.

Synthetic Ligands

Low molecular weight ligands that mimic the action of biologics have gained popularity not only in drug discovery and enzyme inhibition but also in several protein purification applications. The use of synthetic chemistry for the generation of compounds bound to a solid support (resin beads, silica surfaces or plastic pins) or in solution (for latter derivatization) is a fundamental yet powerful tool. However, nonspecific binding is a major disadvantage and has prompted the emergence of rationally designed ligands or biomimetics. These biomimetics have endearing properties such as high stability, defined chemical structure and toxicity, resistance to degradation, inexpensiveness and sterilizability *in situ*. They mimic the action of natural counterparts of proteins and can selectively extract the protein of interest. The devel-

opment of such synthetic molecules has been inspired and aided by the increasing availability of protein structural data and knowledge about protein–ligand complexes.

Synthetic combinatorial libraries comprising several hundreds to tens of millions of compounds are potential sources for drugs, enzyme inhibitors and antimicrobials. Peptidomimetic and organic libraries are yielding compounds to replace biomolecules for easier manipulation of the physical, chemical and biological properties and to address issues related to cost and availability. Oligomeric *N*-substituted glycines (NSG) or peptoids are novel polymers that are also being widely used for generation of vast chemical libraries. They are achiral, protease-resistant, inexpensive and are hydrolytically and enzymatically stable.

Design Rationale

A valuable approach in biotechnology involves the marriage of several technologies for the production of commercially viable diagnostics and therapeutics. The process of exploiting structural analysis, chemical synthesis and advanced computational tools when combined with rational design makes the technology more powerful, faster and logical. Structure elucidation of proteins by X-ray crystallographic and nuclear magnetic resonance (NMR) studies and improvement in software algorithms to generate homology models form the basis for rational ligand or drug design. Software programs provide us with an opportunity to calculate, visualize, formulate and hypothesize about the properties of molecules in terms of energy and orientation in their functionally active three-dimensional state and in complex with putative ligands.

The research strategy for the identification of key ligands typically involves obtaining structural information about the protein of interest, such as crystallographic, NMR or homology data. A target ligand-binding site is then identified on the protein; this may be an active site, a solvent-exposed region or motif on the protein surface or a site involved in binding the natural ligand. A combination of sophisticated modelling software packages and organic synthesis followed by activity analysis helps select a lead ligand. The optimum performance of the ligand is assessed by subjecting it to a range of experimental conditions and/or by constructing a library of near-neighbour ligands and selecting the one with desired key features. A general affinity (K_d) of 10^{-4} – 10^{-8} mol L⁻¹ between the immobilized ligand and the target protein proves satisfactory.

Design Tools

Modelling software can be used to probe properties of the three-dimensional structure of a protein such as charge distribution, key electrostatic interactions, hydrophobicity, hydrogen-bonding sites, extent of surface or solvent exposure of epitopes on the protein surface and identification of cavities, pockets and active sites. This information is essential for the site-directed *de novo* design of the ligand or drug candidates that may form novel leads. However, it is important to remember that proteins are elastic molecules that can bend and twist and even change their conformation upon ligand binding.

With an exponential increase in the availability of protein structures from the Brookhaven database (over 7000 protein entries), several sophisticated programs have emerged for modelling and visualization of molecules in three dimensions. SWISS-PROT, SCOP and the University College London (UCL) protein database (adapted from Protein Data Bank (PDB) files) are further sources for protein structures, with additional features such as LIGPLOTS of protein-ligand complexes. Homology models of proteins can be displayed with programs such as MODELLER that uses probability maps and COMPOSER that first defines the conserved regions, then the variations in structure such as loops and finally the side chains. Automated docking programs like DOCK and LUDI help predict the structure, mode and the binding free energy of the ligand-protein complexes. These programs work in conjunction with chemical structure databases such as the Cambridge Structural Database (Cambridge Crystallographic Data Centre with 110 000 compounds) or the Available Chemicals Database (100 000 compounds). HOOK is another program that generates putative ligands based on the chemical and steric complementarity between the ligand and the binding site on the protein. Calculation of molecular parameters is performed by force fields, with CHARMM, MM2, MM3 and AMBER being the commonly used programs. Force fields give information in terms of classical and mechanical potential energy functions rather than quantum mechanics.

The introduction of combinatorial synthesis has given us the capacity for multiple choices and alternatives. It is imperative not to be misled by the technique and synthesize a whole library of compounds that show no activity and cost money and time to synthesize. There are programs such as PRO-SELECT (SELECT = systematic elaboration of libraries enhanced by computational techniques) that help limit the size of a combinatorial library by using structural constraints on the protein target. Compact

molecular modelling software packages such as QUANTA, SYBYL, MACROMODEL and INSIGHT can be commercially obtained with a choice of energy minimization, autodocking and homology programs. Although there is a jungle of information and programs on drug and ligand design, these algorithms can only provide a certain rationale to rather serendipitous discoveries.

Designer Dyes

In 1968 Haeckel and others observed during gel filtration that Cibacron Blue F3G-A, the textile dye part of blue dextran, bound to pyruvate kinase. This observation subsequently led to the purification of a whole series of proteins and opened a new chapter in the role of textile dyes in protein purification. Dyes usually contain polyaromatic ring systems with electron withdrawing or donating groups and proteins contain a variety of hydrophobic and ionic residues. This complementarity assists in dye-protein interactions. Chlorotriazine dyes are inexpensive, easily synthesized and immobilized on solid support matrices and display a high capacity for proteins. The binding action mimics the binding of natural anionic heterocyclic substrates such as nucleotides, nucleic acids, adenosine triphosphate and coenzymes with enzymes. However, proteins (factor X, thrombin and kallikrein) that bind to cationic substrates have also been reported to bind nonspecifically to anionic dyes. Synthetic dyes have several advantages over biologics, although they can lack specificity. This prompted the *de novo* design and synthesis of biomimetic ligands aimed at specific sites on target proteins.

De Novo Ligand Design and Synthesis

Trypsin-like Family of Enzymes

The trypsin-like family of enzymes requires cationic substrates for their enzymatic action. Common examples are tissue plasminogen factor, factor Xa, thrombin kallikrein and urokinase. These enzymes are known to bind to the side chains of lysine or arginine at a site (primary binding pocket) proximal to the reactive Ser195. The specificity is introduced mainly by the side chain of Asp189 present at the bottom of the primary binding pocket. Secondary interactions formed by amino acids binding adjacent to the primary pocket also confer specificity to individual members of the enzyme family.

Tissue kallikrein, that has kininogen as the natural substrate, shows a marked preference for arginine in the primary binding pocket and phenylalanine on

the secondary site (Figure 1). The phenyl ring of phenylalanine is believed to form hydrophobic interactions with Trp215 and Tyr99. In contrast, trypsin demands less specificity from the secondary site residue. Thus, Burton and Lowe (1992) hypothesized that a structure based on the Phe-Arg dipeptidyl template should be designed and synthesized. The biomimetic ligand consisted of phenethylamine and *p*-aminobenamidine oriented on a triazine scaffold (Figure 2). Since the primary binding pocket of kallikrein lies in a depression, a hexamethylene spacer was introduced between the ligand and solid support to counteract any steric hindrance from the matrix backbone. On performing affinity chromatography with a crude pancreatic acetone powder, the designed synthetic ligand was able to purify kallikrein selectively with 110-fold purification factor. This efficiency compares well with the natural substrate ligands.

Artificial Protein A

Antibodies are used extensively in diagnostics, immunoassays, therapeutics and purifications, and can

be used as probes for labelling and imaging. Monoclonal antibodies, single chain and humanized antibodies have found innumerable applications in most areas of protein chemistry, biochemistry and molecular biology. However, the availability of antibodies in their highly pure form has largely limited their range of application. Immunoglobulins are routinely purified by immobilized staphylococcal protein A (SpA) or by conventional protein purification procedures. The high clinical value of immunoglobulins and disadvantages of using potentially toxic biologics in their purification initiated a remarkable study combining the powerful tools of rational computer-aided modelling and organic synthesis to generate an artificial protein A.

The crystal structure of the Fc domain of IgG and fragment B (Fb) of SpA (Figure 3) shows involvement of a total of 32 amino acid residues over an intersurface area corresponding to 400 nm². The primary forces holding the complex together are hydrophobic, hydrogen bonding and two salt bridges. The hydrophobic stacking is mainly provided by residues

Figure 1 (See Colour Plate 15) Illustration of the molecular model of porcine pancreatic kallikrein with the dipeptidyl motif Arg-Phe occurring in the natural kallikrein substrate, kininogen. The model was generated by manipulating the BPTI-pancreatic kallikrein complex using Quanta 97. The residues in the BPTI inhibitor not involved in the complex were deleted, leaving residues Lys-15 and Cys-14, which were substituted with arginine and phenylalanine respectively. The dipeptide was energy-minimized and its side chains were adjusted to interact with the primary and secondary binding sites, as the Lys-Cys dipeptide does in the BPTI-pancreatic kallikrein complex.

Figure 2 (See Colour Plate 16) Illustration of the synthetic ligand docked in the substrate-binding site of porcine pancreatic kallikrein. The ligand is an analogue of the Arg-Phe dipeptide that occurs in the natural substrate of kallikrein, kininogen, and is responsible for the enzyme-substrate complex. The benzamidine and phenethylamine moieties substituted on a triazine framework mimic the Arg-Phe dipeptide. The ligand was designed and energy-minimized in Quanta 97 and moved in the vicinity of the substrate-binding site, whence the side chains were adjusted to fit in the primary and secondary binding sites in porcine kallikrein. The aromatic ring of phenethylamine stacks in the primary binding site between Tyr-99 and Trp-215 and the benzamidine group forms several interactions with Asp-189, Ser-226, Gly-216, Pro-217 and Thr-218, forming the secondary binding site.

Phe124, Phe132, Tyr133, Leu136, Ile150 and the side chain of Lys154 on SpA and Ile 253 in IgG. Four hydrogen bonds can be identified between the ϵ^2 -amido group of Gln128 (SpA) and the γ -hydroxyl group of Ser254 (IgG), the δ^2 -amido group of Asn130 (SpA) and the δ^1 -carbonyl oxygen of Asn434 (IgG), the η -hydroxyl of Tyr133 (SpA) and the carbonyl oxygen of Leu432 (IgG), ϵ^2 -amido group of Gln311 (SpA) and the δ^1 -carbonyl oxygen of Asn147 (IgG). Salt bridges are formed between the δ -guanidino group of Arg146 (SpA) and the γ -carboxyl group of Asp315 (IgG) and between the ϵ -amino group of Lys154 and a sulfate ion in solution. The hydrophobic core dipeptide Phe132-Tyr133 on a helical twist of the SpA Fb region is oriented to interact with a shallow groove on IgG, comprising residues Leu251, Ile253, His310, Gln311, Glu430, Leu432, Asn434 and His435. This Phe-Tyr dipeptidyl motif is found in four highly conserved regions of SpA and each is capable of interacting with IgG from different species. If the binding pocket in IgG is made more hydrophilic by replacing the His435 with an Arg, the binding with SpA weakens, suggesting the importance of hydrophobic residues in the complex.

Li and co-workers (1998) noticed that this formed an exceptional basis for the design and synthesis of a ligand for the purification of IgG.

The biomimetic ligand (ApA) is comprised of anilino and tyramino substituents, mimicking the binding action of the Phe-Tyr dipeptidyl unit, spatially oriented on a triazine framework acting like the helical twist of SpA (Figure 4). A diethylamino spacer was used to immobilize the ligand on a solid support. This ligand proved to be complementary to the SpA binding site and had an affinity constant of 10^4 mol L^{-1} for IgG. ApA could purify 98% IgG from human plasma and also inhibit the binding between SpA and IgG on enzyme-linked immunosorbent assay. Immobilized ApA showed a capacity of 20 mg IgG per gram moist weight gel. This biomimetic ligand could be further optimized to increase selectivity, capacity and the use of milder experimental conditions. Thus, a combinatorial library comprising 88 adsorbents was constructed for lead optimization of ligand ApA. The synthesis was inspired by the 'mix and split' procedure on a triazine scaffold and was intended to mimic the binding mechanism of ApA with improved features.

Figure 3 (See Colour Plate 17) The complex between the Fb fragment of SpA and the Fc fragment of IgG. The residues in pink represent amino acids in SpA interacting with the residues in yellow in IgG. The residues in green represent the Phe-Tyr dipeptide, key residues in holding the complex. The dotted lines represent inter- and intramolecular hydrogen bonding. The interaction involves a total of 32 amino acids spanning and intersurface area corresponding to 40 nm². The interaction is predominantly characterized by hydrophobic interactions as well as some hydrogen bonding and two salt bridges.

Combinatorial solid-phase synthesis and activity analysis suggested that a biomimetic (22/8) with 3-aminophenol and 4-amino-1-naphthol substituted on a triazinyl scaffold was able to purify IgG selectively from diluted human plasma and eluted more than 99% of bound IgG.

A similar approach was employed to design highly specific ligands for other industrially and clinically important recombinant proteins such as factor VIII and insulin. These designer ligands proved to be highly successful and were able to isolate target proteins from crude fermentation broth with high specific activities and purification factor.

Protein Structural Isoforms

Protein synthesis is accompanied by some important events, termed post-translational modifications, that convert the information carried by a two-dimensional polypeptide into a complex, biologically active three-dimensional protein. These modifications encompass events such as protein folding and phosphorylation, glycosylation, sulfation and myristoylation. Variations in post-translational modifications lead to variants of a protein that are products of the same

gene but may vary in structure, function, pharmacokinetics and pharmacodynamics. Glycosylation, the most important event during protein synthesis, has received much attention in the last few years due to its influence on the clinical and therapeutic properties of proteins. Most biopharmaceuticals produced by recombinant DNA technology, such as erythropoietin and tissue-plasminogen activator for *in vivo* administration, are glycosylated. These may suffer from glycoform heterogeneity due to variations in the carbohydrate sequence or due to variable site occupancy of the sugar moieties on the protein. Consequently, it is important to isolate, resolve and analyse recombinant glycoforms with defined glycosylation and biological properties prior to clinical prescription.

The strategy for the resolution of glycoforms involves generation of synthetic ligands that display affinity and selectivity for the sugar moieties on glycoproteins but have no interaction with the protein *per se*. A detailed assessment of native protein-carbohydrate interactions using molecular modelling tools formed the basis for the synthesis of carbohydrate-binding ligands. The ligands were synthesized on a solid phase and assessed for their sugar-binding ability with glycoenzymes. Chromatography

Figure 4 (See Colour Plate 18) Molecular model between the Fc fragment of IgG and the synthetic ligand ApA. The ligand, in red, is a mimic of the key dipeptide Phe-Tyr, in green, in SpA and comprises anilino and tyramino moieties substituted on a triazinyl framework. ApA is located at the putative binding site among the amino acid residues involved in the interaction between the Fc part of IgG and Fb fragment of SpA.

with partially and completely deglycosylated enzymes, elution of glycoproteins with sugars and inhibition of glycoproteins for the synthetic receptor in the presence of free sugars helped to assess the selectivity of the ligands for the sugars. Palanisamy and co-workers (1999) observed that triazine-based ligands display selectivity for the glycomoiety on glycoproteins and identified mannose-binding synthetic ligands.

Applications

Readers can put their imagination to the test and list innumerable applications for this technology. Reliable and robust synthetic affinity ligands are being used for the purification of several therapeutically and industrially important recombinant proteins for clinical, diagnostic or research purposes. The opportunity to use efficient, nontoxic and highly characterized synthetic compounds is lucrative not only in protein purification but also in localization

(probes) and tagging of macromolecules. A major application is in the removal of contaminants such as endotoxins, misfolded protein conformations, nucleic acids and viruses during recombinant protein production.

The applications of these synthetic low molecular weight ligands as drugs are forthcoming and these highly specific, nontoxic, characterized, inexpensive, easy-to-synthesize and nonlabile compounds could prove to be blockbuster therapeutics. The direct use of these ligands as drugs in diseases such as cancer stems from the fact that during infection there is an increased vasculature for nutrient supply. This is aided by overexpression of certain proteins that, if blocked from interacting with their complementary receptors, could help circumvent tumours.

Application of peptides and oligonucleotides as drugs, high affinity ligands or potent inhibitors is still in its infancy. The problems of low oral activities and susceptibility to hydrolysis has initiated tagging

the products with conjugates such lipophilic agents and polymers that not only reduce degradation but may enable efficient uptake by cells. However, a putative application is in identifying epitopes on proteins for receptor-binding studies, drug design and inhibition of proteases, proteins and oncogenes. In fact, the technology could complement rational ligand design when structural data for proteins are absent.

Bioprocess monitoring is another application that stems from requirements for optimizing cultivation conditions and harvesting times for recombinant protein products in fermentors. Modern bioprocessing demands control of several processing parameters with engineering ingenuity to obtain online monitoring to reduce labour, cost and analysis time. The ability to measure specific macromolecules in a fermentor in the presence of a soup of nutrients, host cell proteins, media components and other impurities requires highly selective and efficient ligands that can also be sterilized *in situ*. The selective biorecognition system, when incorporated with a sensitive transducer for interpreting the biorecognition signal into a comprehensible electric signal, generates a reliable biosensor for online measurements.

Conclusions and Future Prospects

Success in biotechnology and biochemistry is well attributed to developments in analytical techniques and instrumentation. The production of several high value therapeutics would not have gone to completion if it were not for efficient methods in protein purification. Conventional purification techniques are becoming outdated for industrial applications, and technologies based on proteins, peptides and oligonucleotides have gained an impetus, although they are prone to enzymatic and chemical degradation and have short *in vivo* and *in vitro* lifetimes. Peptides and oligonucleotides make undesirable drug candidates owing to poor oral activities. Furthermore, peptides have a large number of conformations that may be highly flexible and which can make attainment of the most favourable conformation and orientation difficult and lead to low affinity ligand-protein complexes.

The current focus is on compounds that lack the repetitive backbone units linked by facile bonds prone to chemical and biological (proteases and nucleases) cleavage. Thus, large number of alternative methodologies have been proposed to replace the peptide bond (peptidomimetics) with the use of peptoids, carbamates, sulfones, alkenes, urea, phosphodiesteres and sulfonamides.

Sophisticated organic synthesis has inspired chemists to synthesize receptors, drugs, peptides, nucleo-

tides and their mimetics to identify epitopes on surfaces of proteins for therapeutic, diagnostic, inhibitory and purification purposes. A combinatorial approach has become the choice of several chemists to maximize the possibility of success for lead generation, optimization and development of candidate drugs or ligands. However, it is very expensive and laborious to produce, screen and manage data for all these compounds. Some direction and rationale is essential. Information about structure-activity relationship lends that extra information that can help in pre-selection.

The availability of fast and sophisticated computer modelling software packages and the marriage of rationale and serendipity makes the design and synthesis a successful venture for investigation. A prerequisite in *de novo* design of biomimetics ligands is the availability of protein structural data and information on protein-ligand complexes. With the advances in proteomics, protein structural availability is hardly a limiting issue. In the coming years, there will be an explosion of protein structural data. The completion of the Human Genome Project will unveil countless new proteins, challenging methodologies such as random screening, rational design, combinatorial chemistry and high-throughput screening to become rapid, inexpensive and fully automated with the incorporation of robotics. Simultaneous developments in data management, proteomics and bioinformatics will integrate the technology and reduce time, cost and labour. The challenge to mimic the action of natural biological recognition is ongoing, and, as nature uses only a repertoire of 20 amino acids to generate an endless combinatorial list of proteins, the challenge for rational ligand design continues.

Theory and Development of Affinity Chromatography

R. Scopes, La Trobe University, Bundoora, Melbourne, Australia

Copyright © 2000 Academic Press

Introduction

The term affinity chromatography began to be used extensively in the 1960s to describe protein separation methods that made use of the specific biological interaction of the desired protein with some ligand that was immobilized on an adsorbent matrix. Since most proteins, and all enzymes, bind to some compound very specifically, this immediately promised to solve most protein purification problems. But, as with all good ideas, there were many cases when it did not work as expected; the general concept of affinity chromatography for purifying proteins found its niche, but was no panacea. More recently, it has found a fairly widespread application in purifying recombinant proteins, using very standardized procedures.

Although most applications have been for proteins, it is not so limited in theory, since other biological macromolecules have specific interactions which can be exploited, especially nucleic acids. But, for the purposes of this article, the principles will be expounded with proteins as the prime target. We should consider the definition(s) of affinity chromatography carefully, since it does not mean the same to everyone. First, the word affinity. Any two components that are attracted to each other can be said to have an affinity, but if we took that as a definition, the term would be too broad to be useful – for instance, it could include all types of chromatography. It is better to limit the definition of affinity to a biologically significant interaction such as between a hormone and its receptor, an enzyme and its substrate, or an antibody and its antigen. Unfortunately, there are well-established uses of the term, such as immobilized metal affinity chromatography, in which

the interaction is not biologically relevant, though it too can be highly specific. Perhaps a better definition could imply simply a high specificity and selectivity of the interaction, though that can exclude some examples of true biological affinity.

The other word, chromatography, strictly means that process in which components are adsorbed and desorbed continuously as they move down a column, or through some other medium, resulting in a multi-stage separation of different components according to their partitioning between the stationary and mobile phases. But affinity methods are usually treated in an 'on-off' fashion in which, after total adsorption of the desired component, a stepwise change in the buffer mobile phase results in its complete elution, and true chromatography is not carried out. Nevertheless, the word chromatography is used more widely than its strict definition, to encompass any use of an adsorbent, even in this 'on-off' fashion.

And so we come up with a definition of affinity chromatography as a chromatographic procedure utilizing an adsorbent involving an immobilized ligand which has a high specificity for binding the desired component, preferably to the exclusion of all others. This binding can be loosened by a change in buffer conditions, to elute the desired component relatively free of contaminants. If the ligand is the natural biological ligand of the desired component, then the more precise term bioaffinity chromatography can be used. On the other hand, when the interaction is specific, but the ligand is unnatural, terms such as pseudo-affinity chromatography and biomimetic chromatography have been adopted.

Early Developments in Affinity Chromatography

The first protein to be purified by affinity chromatography was amylase in 1910, for which a column

packed with starch was used. Presumably the column disintegrated during the process! Attempts were made in the 1950s to link antigens to cellulose columns for the purification of antibodies, but these were not very successful because of the low capacity of the cellulose matrix. Unless the particles used to pack the column are permeable to the proteins, only the surface of the particles is available for attachment. The more successful applications commenced when suitable protein-permeable particulate materials were developed, together with reliable chemical methods that could be used for attaching specific ligands to these materials. Much of the original work was based on the use of cyanogen bromide as a method for activating the matrix, and the use of agarose beads as the support material. Agarose has almost ideal properties, in that the gel formation of the beads has pores permeable to most proteins, so that the internal volume of the beads is all available for attachment, as well as the outside surface. Moreover, agarose in itself has virtually no affinity for any protein (other than agarases), so nonspecific binding is rarely observed. It is still the matrix of choice for most affinity chromatography, though there are now many competing materials, both polysaccharide-based and synthetic.

Activation of the matrix involves treating the material with a chemical that introduces a group (normally reacting with hydroxyls on polysaccharide matrices) which itself will then react with something, usually an amine, in the ligand to be used. All such activating chemicals are extremely reactive and dangerous to handle, especially those that are volatile. Cyanogen bromide reacts to introduce several forms of cyanate derivatives, of which the cyanate ester is the most important. This ester will couple to a primary amine, such as a lysine residue in a protein, to produce the isourea-linked ligand (Figure 1).

Figure 1 Activation of a carbohydrate matrix with cyanogen bromide. The major product is the cyanate ester after reaction with a primary hydroxyl group. This rapidly couples with an amine to produce the isourea structure, which is positively charged at neutral pH.

Cyanogen bromide activation is still widely used, and the dangerous chemistry is overcome by having the already-activated agarose available as a commercial product. However, it does have some disadvantages compared with other methods outlined below—in particular, the instability of the isourea linkage.

Many other activation methods have been developed, and a brief summary of these is given in Table 1. Several of these incorporate a bifunctional reagent, one end of which combines with the matrix, and the other with the ligand. These may cause some cross-linking within the matrix, but this can be advantageous for matrix stability. Bifunctional reagents also introduce a spacer arm (see below) of various lengths depending on the reagent. The activated matrix then reacts with a nucleophile such as an amine, or in some cases a sulfhydryl group in the ligand being coupled (Figure 2A).

The ligands exploited at first were mainly enzyme substrates. In particular, so-called group-specific ligands were developed which could be used for a variety of different enzymes having the same

Table 1 A selection of activation methods, and the properties of the spacer arms introduced after coupling with amino-reactive ligand. A positive charge can result in some nonspecific anion exchange behaviour at low ionic strengths. Cleaning of protein adsorbents is best carried out with alkali, but many linkages are alkali-labile

Reagent	Spacer arm length, atoms	Type of linkage	Charge at pH 7	Alkali lability
Cyanogen bromide	1	Isourea	+	Yes
Carbodiimide	1	Amide	0	Yes
Epichlorohydrin	3	Secondary amine	+	No
Bisoxirane	11	Secondary amine	+	No
Divinyl sulfone	5	Secondary amine	+	Yes
Tosyl/tresyl	0	Secondary amine	+	No
Hydroxy-succinimide	8 ^a	Amide	0	Yes
Cyanuric chloride	4	Aromatic amine	0	No

^aDepends on activation reagents.

Figure 2 (A) Activation of a matrix with a bifunctional reagent, which provides a spacer arm. (B) Coupling of a ligand containing a built-in spacer arm to an activated matrix.

substrate – more particularly, a common cofactor. Thus we had, and can still purchase, adsorbents containing nucleotide cofactors such as ATP and NAD, lectins for glycoproteins and nucleic acids for binding either other nucleic acids or enzymes involved in nucleic acid metabolism. The use of affinity chromatography which exploits the interaction between an antibody and its antigen has been extensively developed, and is described in detail elsewhere.

The main problems associated with affinity chromatography soon appeared. These can be summarized as:

1. It took a long time to develop an adsorbent that does the job.
2. Once made, the adsorbent is expensive and has a limited useful life.
3. There is nonspecific binding of unwanted proteins.
4. There is a need for spacer arms.
5. There are difficulties in satisfactory elution.

Many of these problems have now been solved, with a clearer understanding of the important factors involved. It is now not often that a completely new adsorbent has to be developed. The expense parameter is less important on a research scale, but is a major consideration in large scale commercial purification. The related problems of nonspecific binding and spacer arms can usually be overcome by judicious

process design, and elution procedures for the more difficult tasks such as antibody–antigen interactions are now better established. Even so, there are many cases in which a workable true affinity method cannot be established, usually because the natural affinity may be very specific, but quantitatively weak.

Spacer Arms

The need for spacer arms was realized early on, since placing the ligand directly adjacent to the matrix might sterically hinder the interaction with the protein (Figure 3). But it has been shown that, as most spacer arms are hydrophobic, they can interact with other parts of the protein in a relatively nonspecific way. This has both advantages and disadvantages: the advantage, as described below, is that these nonspecific hydrophobic interactions can add to the binding strength of otherwise weak, though highly specific, interactions between a protein and its natural ligand. When inert, i.e. hydrophilic, spacer arms were introduced, many previously successful affinity methods did not work because the binding of the desired component was now too weak. The disadvantage of the use of spacer arms is that hydrophobic interactions with unwanted proteins may be so strong that these proteins may be bound as well.

Figure 3 Demonstration of the role of a spacer arm in keeping the bound protein away from the matrix backbone. Without the arm, it may be impossible for the protein to interact with the ligand, *W*.

Spacer arms can either be introduced as part of the activation process (see **Table 1**), or added afterwards in a multi-step process of creating the adsorbent. Sometimes it is beneficial to synthesize chemically a suitable spacer arm (ending with an amine) attached to the ligand itself, when the ligand does not have a suitable active nucleophile for direct coupling (Figure 2B).

Thus, spacer arms have two possible functions in a successful affinity adsorbent. First, they place the ligand away from the matrix to avoid physical interference from the matrix backbone. Second, they can provide some weak nonspecific interactions that increase the overall binding energy so that adsorption is more complete.

Some Quantitative Parameters

For a protein to bind to an adsorbent in a column, it must have sufficient affinity (in the broadest sense) to partition to the solid phase. It need not be an absolute adsorption; the protein can be in a dynamic state between being adsorbed and in solution. An equilibrium can be established provided that the flow rate is not too great, and an equilibrium constant defined between the matrix binding sites and the protein itself. We can call this the affinity constant, equal to the association constant between the protein and the adsorbent. If the protein is to bind to the adsorbent, it must spend most of its time ($> 90\%$) in the adsorbed state so that its progress down the column is greatly delayed. We can calculate that, for strong binding the affinity constant will typically need to be at least in the range 10^{-5} – 10^6 mol L $^{-1}$. Alternatively, the reciprocal of this value may be expressed as a dissociation constants – 10 μ mol L $^{-1}$. It is useful to use dissociation constants, since they can be related to an enzyme's Michaelis constant value, which is easily determined from the enzyme's activity at different substrate

concentrations. The value of the required affinity constant depends very much on the effective concentration of binding sites in the matrix. Although the concentration of ligand attached to the matrix may be quite high, for steric reasons it is usually the case that only a small percentage are actually available for binding.

Since many enzymes do not bind their substrates with micromolar affinities, it appears that true affinity chromatography is often not possible. Nevertheless, it was soon discovered that strong binding could be obtained despite relatively high dissociation constants (i.e. weak binding) for the free ligand and the protein, and successful procedures could be developed. This was because nonspecific binding, mainly due to spacer arm interactions, increased the overall adsorption.

If we define a binding free energy for the biospecific interaction as ΔG_s^0 , and for nonspecific interactions as ΔG_n^0 , then the total binding energy is the *sum* of ΔG_s^0 and ΔG_n^0 . But the effective dissociation constant is equal to the *product* of K_{ds} and K_{dn} , the constants for the specific and nonspecific interactions. A very weak nonspecific interaction in addition to the biospecific one can tip the balance between adsorption and nonadsorption.

This theory describing an affinity constant is rather simplistic, because in fact any adsorbent will have a range of affinity constants according to the accessibility of the individual ligands. There will be some tight-binding sites which are occupied first, and weaker ones will be occupied as more sample is applied. There may be some bleeding of protein from the weakest sites as the column is washed. A further complication is the possibility of multi-point attachment, in which an enzyme made up of two or more subunits, each with a binding site, may be held by two or more ligands. Such binding would be very strong, only likely at high matrix ligand concentrations (> 20 μ mol mL $^{-1}$). All such theoretical treatments assume that equilibrium conditions exist: this is only an approximation at the flow rates that are commonly employed, and some diffusional processes are so slow that the equilibrium assumption is far from valid.

In order to elute the protein from the column, the binding must be weakened. In most cases, a decrease of ΔG_s^0 is sufficient, and this can be done by either nonspecific buffer changes such as increased salt concentration, or by specific methods (see below).

Types of Ligand

In theory, any molecule can be used as a ligand in affinity chromatography, from small ones like

amino acids to large proteins and even supramolecular fragments such as membranes or whole cells. It must be possible to immobilize the ligand in such a way that it is still recognized by its biological partner. Thus, a random attachment of an antibody through lysines will allow only a small proportion of the antibody molecules to be oriented in an appropriate way to bind with their antigen, but a more directed attachment, for instance through the carbohydrate moiety on the Fc fragment, can increase this proportion significantly. Attachment of a ligand through an amine that is part of the biological recognition site will not produce a satisfactory affinity adsorbent, and some subtle chemistry may be needed to synthesize a ligand derivative that attaches elsewhere.

Highly specific adsorbents which are expected to interact with only one protein are the ideal, but may need to be synthesized individually (antibodies are a good example of this). On the other hand, group ligands which are expected to interact with a range of different proteins will obviously be less specific, but can be used for a wide range of different purifications. Not surprisingly, it is the latter which tend to be available commercially. An example is AMP-agarose, which interacts with enzymes that have ATP or NAD^+ as substrates. Despite the fact that AMP itself binds very weakly to most such enzymes, the additional nonspecific hydrophobic interactions with the hexyl spacer arm create sufficient binding energy. Lectins, such as concanavalin A which specifically binds to mannose residues in glycoproteins, have been extensively employed. Pseudo-affinity group adsorbents such as dye ligands have many advantages, including simplicity of synthesis.

Possibly the best known types of affinity adsorbents are antibodies, for purification of antigens; protein A and protein G for purification of antibodies; and an increasing range of affinity and pseudo-affinity materials for purification of recombinant fusion proteins. This last group will be discussed below, and antibodies (immunoaffinity chromatography) are described elsewhere.

The Matrix

The vast majority of affinity chromatography adsorbents have made use of agarose as the base material, or matrix. Beads of diameters between 40 and 150 μm have been the most popular, and the agarose cross-linked to provide increased rigidity and temperature stability. But there are several propriety matrices, mostly synthetic materials, that are available as alternatives. These have mainly been developed as

high resolution, high performance adsorbents as ion exchangers, and have the desirable properties such as fast flow rates, uniform bead diameters and rigidity under high pressure conditions. These are properties that are not often relevant to affinity methods, and at least on a large scale the extra cost of these materials compared with agarose may not be justified. It is always important that there should be a minimum of adsorption of proteins on the matrix itself, and carbohydrates such as agarose satisfy that requirement better than most other materials. Although we usually talk about affinity columns, there are several other ways of using an affinity adsorbent apart from in a column. Batchwise processing can be very successful if the affinity interaction is sufficiently strong, and other configurations include stacks of membranes as matrix, with the sample being forced through the membranes under pressure.

The Elution Step

General Elution

Having bound the desired protein to the affinity column, it must now be eluted. The standard way with simple ligands is to increase the salt concentration, or use a radical shift in buffer pH. This normally interferes with natural bonding between protein and ligand, thereby weakening the affinity constant between the two. But there are many cases in which increasing salt concentration is not appropriate, especially with antibody-antigen interactions. If the adsorption has a high hydrophobic contribution, then increasing salt concentration may increase the strength of binding. In that case elution may be achievable by a very low ionic strength buffer, in combination with a slightly alkaline pH. Nonionic detergents may also assist. With immuno-adsorbents the elution is carried out by partially denaturing the antibody at low (2) or high (10) pH, or by chaotropic (structure-destabilizing) agents such as guanidine hydrochloride or sodium thiocyanate. The antigen is released, but if it is a protein, it might be denatured under these conditions.

Complete elution of all the protein from the column is fine if the adsorption has been specific, and only the desired component has been bound. But if unwanted proteins are bound in addition to the target component, then a more selective method is appropriate. The buffer conditions are adjusted so that the desired component is not quite eluted, but other proteins are, giving a preliminary clean-up. Then the conditions are adjusted again so that the desired component is just eluted, but other proteins remain on the

column. Sometimes this can be useful, but it is far preferable to use affinity techniques at the elution stage as well as at the adsorption stage.

Affinity Elution

Although it is hoped that only the desired component will bind to an affinity column, in many cases this is not so. For example, when a group adsorbent such as a nucleotide is used, there are likely to be many different enzymes with an affinity for that nucleotide which will bind to the column, and pseudo-affinity adsorbents such as dyes bind many proteins nonspecifically. Because of this, use of an affinity procedure during the elution can be highly beneficial. The principle is simple: free ligand is included in the elution buffer, and displaces the adsorbed protein from the immobilized ligand (Figure 4). The technique is called affinity elution, or biospecific elution. The displacement may occur at different pHs, different ligand concentrations, or salt concentration for each specifically bound protein that is on the column, since each is likely to have a different affinity constant. Thus, it is possible to elute the desired protein under conditions when few, if any, of the others accompany it. By applying affinity concepts at both the adsorption and the elution stages, a high degree of purification is obtained. The concentration of ligand used in the elution buffer must be sufficient to compete with the immobilized concentration, and generally at least 10 times the natural dissociation constant should be used. This can be quite costly on a large scale with some ligands.

Affinity elution is also valuable when the adsorption stage has been even less specific. The general concept of adding the ligand to the elution buffer so as to cause the desired protein to come off does not in itself dictate how the protein was bound in the first place. In fact, affinity elution has been very successful even with ion exchange adsorbents.

The best examples are with cation exchangers, when binding of a negatively charged ligand decreases the strength of binding of the positively charged protein to the adsorbent. But the most generally used adsorbents in which affinity elution is applied are the pseudo-affinity dye adsorbents.

Affinity Chromatography of Recombinant Proteins

During the last few years the use of affinity chromatography has become very widespread due to the ability, using molecular biology techniques, to modify proteins so that they can bind to specific adsorbents. The basic principle is illustrated in Figure 5. The gene encoding the protein is fused to DNA which encodes either a complete protein or a polypeptide that is to be used in the affinity process. The expressed protein is then readily purified from the host proteins by passing through the appropriate affinity adsorbent. Since only one adsorbent is needed for each particular system, one laboratory may use the same adsorbent for all its protein purifications. A brief list of some of the combinations of fusion/adsorbent is given in Table 2. These are all commercial products, and there is considerable competition, with new ones being introduced all the time. A popular term for the system is affinity tagging, with the tag being the fusion part. No one system is ideal for all proteins. In particular, the level of expression obtained can be dependent on the fusion type, and the maximum possible expression is required to optimize the overall process.

The end-product of the purification is not the original protein, but a fusion with the added protein or polypeptide. For many purposes this product is good enough, but there are methods of removing the fusion portion, generally by proteolysis. Vectors for creating fusion proteins include an amino acid sequence that is

Figure 4 Principles of affinity elution. The specifically bound protein is displaced by binding preferentially with the free ligand, W , present in the elution buffer. Other proteins which may be adsorbed nonspecifically do not interact with ligand W , and so remain on the column.

Figure 5 Principle of affinity tagging. The protein is expressed in recombinant form with an extra polypeptide tag. This may be a few amino acids, or may be a complete protein. The affinity adsorbent recognizes the tag, whereas untagged proteins are not adsorbed. The tag may be removed with a protease, either while still on the column, or after elution.

recognized by a highly selective proteolytic enzyme such as a blood-clotting factor. Treatment with this enzyme, either before or after the fusion protein has been eluted from the affinity column, releases the original protein, though still with a few extra amino acids in most cases.

Future Developments

We may assume that current trends will continue. As the number of gene sequences continues to expand, with the completion of the human genome project not far off, not to mention the many other genomes being sequenced, there will be more demand to ex-

press and purify these gene products. In many cases the actual nature of the protein will be unknown, with no assay available. By having a reliable fusion system, as outlined above, gene products can be isolated without knowing what their biological function is. So the use of standard affinity materials will be a major item in protein purifications in the near future. But there will still be a need for the more personal affinity system, for studying and isolating components of protein-protein or protein-DNA interactions. For this, the researcher needs a reliable activated matrix (such as those that have been commercially available for many years), to which to add the protein or DNA and get instant attachment.

Table 2 A selection of affinity tagging systems available commercially. Most tags are placed at the N-terminus of the expressing protein, but some, notably the hexahistidine, can be placed at either end

<i>System: fusion protein</i>	<i>Affinity adsorbent</i>	<i>Size of fusion (kDa)</i>
Hexahistidine	Immobilized metal: Ni or Co	1–2
Glutathione S-transferase	Glutathione	26
Maltose-binding protein	Amylose	38
Cellulose-binding domain	Cellulose	35
T7 Polymerase (peptide)	Monoclonal antibody	1
Protein A (partial)	IgG	14
Biotinylation site	Streptavidin	1
Various epitopes	Monoclonal antibodies	1 +

CENTRIFUGATION

Analytical Ultracentrifugation

J. L. Cole, Merck Research Laboratories, West Point, PA, USA

Copyright © 2000 Academic Press

Analytical ultracentrifugation (AUC) involves the measurement of the radial concentration gradients of molecules created by the application of centrifugal force. In contrast to preparative centrifugation, which is used to fractionate mixtures, AUC is a purely analytical technique. Since the pioneering work of Svedberg and associates in the 1920s, AUC has been employed to characterize the mass, size, shape and association properties of macromolecules in solution. The technique has been broadly applied to research problems in biochemistry, molecular biology and polymer sciences and has also found practical applications in the pharmaceutical and biotechnology industries. Some of the most attractive features of AUC are:

1. Versatility: a wide variety of samples can be examined by AUC, including molecules ranging in size from sucrose to virus particles.
2. Rigor: AUC experiments are directly interpreted in the context of thermodynamic and hydrodynamic theory, so it is not necessary to run standards to calibrate each experiment.

Also, because the experiments are performed in free solution there are no complications due to interactions with matrices or surfaces that can complicate interpretation of other types of measurements.

3. Convenience: recently, new instrumentation (Beckman Coulter XL-A and XL-I) and data analysis methods have made AUC much more convenient and accessible to the general biochemistry and polymer science communities. In contrast to earlier instruments, experiments are easy to set up and centrifugation parameters and data acquisition are all under computer control. In addition, powerful desktop computers and new software have greatly accelerated the data analysis process and have also extended the capabilities of AUC.

A complete treatment of the theory and applications of AUC is beyond the scope of this article, and the interested reader is referred to the Further Reading section.

Theoretical Background

The analytical ultracentrifuge is used to perform two different types of experiments, referred to as sedimentation velocity and sedimentation equilibrium. Sedimentation velocity is a hydrodynamic technique and is sensitive to both the mass and shape of a macromolecule. It can be used qualitatively to

Figure 1 Sedimentation velocity of HIV-1 integrase catalytic core domain. Protein concentration 5.4 mg mL^{-1} in 20 mmol L^{-1} Tris, pH 7.5, 500 mmol L^{-1} NaCl, 1 mmol L^{-1} EDTA, 5 mmol L^{-1} DTT. Data obtained at 4°C at a rotor speed of $50\,000 \text{ rpm}$. Radial absorption scans are recorded at 250 nm at 5 min intervals. The rate of movement of the boundary is determined by the sedimentation coefficient, s , and the spreading of the boundary reflects the diffusion constant, D .

characterize sample homogeneity and quantitatively to define mass and shape parameters of the molecular species present in a sample. The experiments are based on simple physical principles. Application of a strong centrifugal field (high rotational velocity) leads to the net movement of solute molecules away from the air-solvent interface (the meniscus) and towards the bottom of the cell, giving rise to a moving boundary (Figure 1). Radial scans are recorded at regular time intervals, and the data are analysed to determine both the rate of movement and broadening of the boundary as a function of time. For a homogeneous sample, a single boundary forms; for mixtures, either a single or multiple boundaries may be resolved. In quantitative terms, the rate of sedimentation of a macromolecule, $v = dr/dt$, is proportional to the force $\omega^2 r$, where r is the radial distance from the centre of rotation, t is time, ω is the rotational velocity. The ratio $v/\omega^2 r$ is defined as the sedimentation coefficient, s . The sedimentation coefficient has the units of time, and is expressed in Svedberg (S) units ($1 \text{ S} = 10^{-13} \text{ s}$). The sedimentation coefficient may depend on concentration so it is customary to extrapolate s to zero concentration, to give s^0 . In addition, to allow comparison of sedimentation coefficients obtained in different solvents and at different temperatures, s^0 is usually corrected to standard conditions (pure water at 20°C) using the following equation:

$$s_{20,w}^0 = s^0 \left(\frac{(1 - \bar{v}\rho)_{20,w}}{(1 - \bar{v}\rho)_{T,b}} \right) \left(\frac{\eta_{T,b}}{\eta_{20,w}} \right) \quad [1]$$

where \bar{v} is the partial specific volume of the solute, ρ is the density of the solvent and η is the viscosity of the solvent. The subscript 20,w refers to properties measured at 20°C in water, and subscript T,b refers to properties measured at temperature T in a buffer solution b .

The sedimentation coefficient is related to molecular properties according to the following equation:

$$s = \frac{M(1 - \bar{v}\rho)}{N_0 f} \quad [2]$$

where M is the molecular mass, f is the frictional coefficient (which is related to macromolecular shape and size), and N_0 is Avogadro's number. The solvent parameters ρ and η are experimentally measurable or can be calculated from the solvent composition using tabulated data. For proteins, \bar{v} can be calculated with reasonable accuracy from the amino acid composition. Any further interpretation of the sedimentation coefficient requires an independent way to measure either M or f . Fortunately, the frictional coefficient is available from the sedimentation velocity data itself. During a velocity run the boundary not only moves towards the cell bottom but also becomes broader due to diffusion. Thus, in addition to measurement of the sedimentation coefficient, s , sedimentation velocity data can also be analysed to obtain the diffusion constant, D . According to the Einstein relationship, the diffusion constant is inversely proportional to the frictional coefficient:

$$D = \frac{kT}{f} \quad [3]$$

where k is the Boltzmann constant and T is the absolute temperature. Combining eqns [3] and [4] one obtains the Svedberg equation:

$$\frac{s}{D} = \frac{M(1 - \bar{v}\rho)}{RT} \quad [4]$$

where R is the gas constant. Thus, measurement of both s and D for a homogeneous sample in a sedimentation velocity experiment provides an independent method of obtaining the molecular mass. Given the mass, the frictional coefficient contains information about the shape and hydration of the molecule. Traditionally, frictional properties have been interpreted by modelling a macromolecule as a hydrated ellipsoid. However, more detailed, structure-based hydrodynamic calculations of frictional properties can now be readily performed using bead models.

In contrast, to sedimentation velocity, sedimentation equilibrium is a thermodynamic technique that is

Figure 2 Sedimentation equilibrium of a 13 base pair DNA sequence. Continuous line, single-stranded; dotted line, double-stranded. 10 mmol L⁻¹ Tris, pH 7.5, 50 mmol L⁻¹ NaCl, 15 mmol L⁻¹ KCl, 0.1 mmol L⁻¹ EDTA, 2 mmol L⁻¹ Spermidine. Data obtained at 4°C at a rotor speed of 40 000 rpm. Radial absorption scans recorded at 260 nm. The molecular mass of the duplex DNA is twice that of the single-stranded form.

sensitive to the mass but not the size or shape of a macromolecule. Equilibrium sedimentation is a rigorous and very accurate method of determining the molecule mass and association state of macromolecules. It is also one of the best methods of defining reversible interactions of macromolecules in solution. Sedimentation equilibrium is performed at lower rotor speeds than sedimentation velocity experiments. When the centrifugal force is sufficiently small, the process of diffusion significantly opposes the process of sedimentation and a stable, smooth, equilibrium concentration distribution of macromolecules will eventually be obtained throughout the cell (**Figure 2**). For an ideal, homogeneous macromolecule, the radial equilibrium distribution is a simple exponential function of the buoyant mass of the macromolecule, $M(1 - \bar{v}\rho)$:

$$c(r) = c_0 \exp[M(1 - \bar{v}\rho)\omega^2(r^2 - r_0^2)/2RT] \quad [5]$$

where $c(r)$ is the sample concentration at radial position r and c_0 is the sample concentration at an arbitrary reference radial distance r_0 . Deviations from the simple exponential behaviour described by eqn [5] can result from the presence in the sample of either multiple noninteracting or interacting macromolecular species, or thermodynamic nonideality. For heterogeneous, polymeric systems, various molecular weight averages (M_n , M_w and M_z) are obtained by appropriate transformations of the data and are used to assess polydispersity and self-association behaviour. In the context of protein biochemistry, the data are usually analysed in terms of discrete oligomeric species, and equilibrium AUC is an excellent method

to determine the native association state of proteins. In the case where discrete oligomeric species are in reversible equilibrium, the stoichiometries (N), equilibrium constants (K_{eq}) and even the thermodynamic parameters (ΔH , ΔS) that define the interactions can be obtained using appropriate data analysis methods.

Instrumentation and Experimental Considerations

In addition to the drive system common to all ultracentrifuges, the analytical ultracentrifuge contains optical detection systems capable of directly measuring the sample concentration inside the centrifuge cell as a function of radial distance during sedimentation (**Figure 3**). The data can be viewed, or even analysed, in real time as the experiment progresses. The Beckman Coulter XL-A uses an absorbance optical system based on a xenon flashlamp and a scanning monochromator that allows measurement of sample concentration at wavelengths ranging from 200 to 800 nm (**Figure 3A**). More recently, Rayleigh interference optics were added, creating an analytical ultracentrifuge, the XL-I, that can simultaneously record data using both optical systems (**Figure 3B**). The Rayleigh interference optical system measures sample concentration based on refractive index changes. Each optical system has certain advantages and disadvantages. Absorption optics are particularly sensitive for detection of macromolecules containing a strong chromophore. Also, for samples containing two or more components with different absorption spectra (i.e. protein and nucleic acids), data can be obtained at multiple wavelengths during the same experiment to selectively monitor each chromophore. The Rayleigh interference optical system is used to analyse macromolecules lacking convenient chromophores (e.g. polysaccharides), as well as samples that contain strongly absorbing buffer components. It is also the optical system of choice for characterizing very concentrated samples. The data from each cell are acquired simultaneously on a CCD camera by the interference optical system, and the resulting rapid collection of large amounts of data is especially useful for certain types of sedimentation velocity experiments (see below). Interference optics are also useful for sedimentation equilibrium experiments that require a higher radial resolution than is provided by the absorbance optical system.

In AUC, the samples are contained in specialized cells which consist of a centrepiece containing channels to hold sample and reference solutions sandwiched between two quartz or sapphire optical windows. The optical pathlength is determined by the thickness of the centrepiece, and is typically 1.2 or

0.3 cm. Sample requirements are fairly modest and preparation is straightforward. It is a nondestructive technique, so the sample can be recovered following the experiment. For sedimentation velocity experiments a two-channel centrepiece is typically used (Figure 4A) and sample volumes of $\sim 420 \mu\text{L}$ are required. For sedimentation equilibrium experiments, the time to achieve equilibrium is inversely proportional to the square of the height of the sample column, and it is advantageous to use shorter columns. A commonly used centrepiece for this experiment contains three pairs of sample and reference channels requiring about $110 \mu\text{L}$ to produce a 3 mm column

(Figure 4B). The sample concentrations used depend on the nature of the macromolecule that is being examined, the sensitivity of the optical system and the analysis method. For charged macromolecules, the ionic strength should be at least 50 mmol L^{-1} to avoid nonideality due to charge effects. Samples should be equilibrated with buffer using either dialysis or gel filtration, and the equilibration buffer should be loaded into the reference sector. Analytical centrifuge rotors are available that hold either three or seven cells together with a reference cell used for radial calibration purposes (four-hole and eight-hole rotors, respectively).

Figure 3 Optical systems in the Beckman XL-I analytical ultracentrifuge. (A) Absorption system. Light from a xenon flash lamp passes through a grating monochromator and is directed on to a sample/reference cell assembly. The transmitted light passes through a movable slit assembly and is detected with a photomultiplier tube. (B) Interference system. 675 nm light from a laser passes through a pair of slits and on to the sample and reference sectors. A series of lenses and mirrors combine the image of the sample and reference sectors to produce a fringe pattern which is imaged on a CCD camera. Refractive index changes result in vertical displacement of the fringe pattern.

Figure 3 *Continued*

Data Analysis Methods

In order to extract the rich information that is available from AUC experiments it is necessary to use the appropriate data analysis methods. In recent years, new approaches have been developed for the analysis of both sedimentation velocity and equilibrium data. Many of these methods are implemented in software that can be downloaded over the Internet or in commercially available packages. Although much of the analysis software is deceptively simple to use, the fitting algorithms are often complicated. In order to obtain physically meaningful parameters from analysis of AUC data it is important for the user to have a good understanding of the underlying principles along with an appreciation of the limitations in the fitting procedures.

Sedimentation Velocity

In the case of a simple, homogeneous macromolecule, analysis of sedimentation velocity data provides s , the sedimentation coefficient, and D , the diffusion constant. Under favourable conditions, it is possible to extract s and D for mixtures of non-interacting macromolecular species, provided that boundaries for each species can be resolved or deconvoluted. The situation is more complicated for reversibly associating mixtures, since it is generally not possible to assign individual boundaries to discrete species.

A traditional method for analysis of sedimentation velocity experiments is to plot the natural logarithm of the boundary position versus time. The slope of this line is proportional to $\omega^2 s^*$ where s^* represents

Figure 4 Sedimentation velocity and equilibrium cell designs. (A) Two-sector velocity cell. Sample is loaded into the upper sector and reference solution (buffer) is loaded into the bottom sector. The sample is centrifuged at high rotational velocity, generating a boundary that moves towards the bottom of the cell. (B) Six-channel equilibrium cell. Three sample reference pairs are loaded into the cell, which is centrifuged at moderate rotational velocity, resulting in equilibrium concentration gradients in each sample channel.

an apparent average sedimentation coefficient. This approach does not provide information about the homogeneity of the sample or the diffusion constant. Consequently, a number of analysis methods have been developed that involve analysis of the entire boundary region. In 1978, van Holde and Weischet described a transformation procedure for removing the effect of diffusion from the boundary. It is particularly useful to determine homogeneity and to detect nonideal behaviour. More recently, Stafford described a time-derivative method for analysis of velocity data in which the time-invariant noise is removed by a subtraction procedure, resulting in a great increase in the signal-to-noise ratio. This approach is particularly useful in the analysis of data obtained with the interference optics, making it feasible to work at very low protein concentrations (e.g. $10\text{--}100\ \mu\text{g mL}^{-1}$). Finally, there are methods for analysis of velocity experiments that involve directly fitting the scan data using either approximate or numerical solutions to the Lamm equation to determine both s and D . The Lamm equation is the partial differential equation that describes transport of solute(s) in the sector-shaped cells used in sedimentation velocity experiments. This approach can be used to fit data using single or multiple species models. Recently, Schuck has described a fitting algorithm which removes the radially-invariant and time-invariant noise contribution from the data, which makes

this method particularly useful for data obtained with the interference optics.

Sedimentation Equilibrium

As in the case of sedimentation velocity, methods for analysis of sedimentation equilibrium data can be divided into model-independent and model-dependent approaches. Model-independent methods are most useful to survey sample properties qualitatively, or for analysis of complex samples, i.e. polymeric mixtures, that cannot easily be described in a model-dependent analysis. In contrast, model-dependent analysis involves direct fitting of the sedimentation equilibrium concentration gradients to relevant physical models (e.g. single ideal species, noninteracting mixtures or a reversible association). This method provides the best-fit values and the associated statistical uncertainties in the fitting parameters (e.g. molecular mass, oligomer stoichiometry and association constants) and a statistical basis to discriminate among alternative physical models.

The simplest model-independent approach to obtain the molecular mass, M , is to plot $\ln c$ versus r^2 . According to eqn [5], the slope of this line is equal to $M(1 - \bar{v}\rho)\omega^2/2RT$. Although linearity of this plot has been taken as evidence that a sample contains a single ideal species, this method can be quite insensitive to heterogeneity, particularly if the concentration

gradient is shallow. Additionally, $d(\ln c)/dr^2$ can be calculated on a point-by-point basis to create a plot of the apparent weight-average molecular weight ($M_{w,app}$) versus concentration. For a homogeneous sample, $M_{w,app}$ will be constant as a function of concentration. An increase in $M_{w,app}$ with concentration indicates mass action-driven association. In this case, it is useful to overlay on the same plot data obtained from several samples over a range of loading concentrations and/or rotor speeds. For a reversibly self-associating system, all of the data will lie on a smooth curve, whereas for a noninteracting or slowly equilibrating system, the data will give rise to a family of nonsuperimposable curves. Other molecular weight averages (M_n , M_z) can also be obtained and can be useful in the analysis of associating systems or polymeric mixtures.

In model-dependent methods, a single experiment concentration gradient, or preferably, multiple concentration gradients, are fit to a physically relevant model using a nonlinear least-squares algorithm. In the simplest case of a single ideal species, data are fit to eqn [5]. For samples where there are more than one species in solution, or if thermodynamic nonideality is appreciable, it is necessary to fit the data to functions containing additional terms to incorporate sample heterogeneity, equilibrium association reactions or virial coefficients. Often it is difficult to distinguish between several models that fit the data equally well. In these cases, it is often useful to employ global methods in which multiple data sets that are collected over a wide range of sample loading concentrations and rotor speeds are simultaneously fit to a specific model. This global fitting approach helps to ensure that a unique solution is obtained and greatly reduces the statistical uncertainty in the parameters. Global nonlinear least-squares fitting of sedimentation equilibrium data was originally implemented in the NONLIN algorithm, and now several programs are available. In addition, equilibrium data are often fit using models programmed by the user within a general-purpose data analysis package.

Conclusions

AUC is a robust and widely accepted analytical method to characterize the molecular mass, size, shape and association of molecules in solution. It has been used extensively by biochemists and molecular biologists to define properties of biological macromolecules and has also found applications within the polymer science community. Experiments are performed using specialized centrifuge cells in an analytical ultracentrifuge capable of measuring radial

concentration gradients using absorption or refractometric optics. In sedimentation velocity experiments a moving boundary forms upon application of a high centrifugal force. The rate of movement of the boundary is determined by the sedimentation coefficient and the broadening of the boundary with time occurs because of diffusion. The sedimentation coefficient is a function of a molecule's mass and frictional properties whereas the diffusion constant is only determined by the frictional properties. Sedimentation equilibrium measurements are performed at lower rotation velocities where the sedimentation force is balanced by diffusion. The shape of the concentration gradient is determined by the molecular weight of the species present in the sample. A variety of computer data analysis methods have been developed for both sedimentation velocity and equilibrium data.

Introduction

Industrially, centrifuges are used for a variety of purposes related to separation of materials on the basis of density. This separation usually involves separation of insoluble particulates from supernatant liquids, but can also include extraction of dissolved substances from one immiscible liquid to another of different density, separating the mixed liquids centrifugally. The blending of the liquids, transfer of the solute and separation of the immiscible phases are sequentially carried out in the same machine at high speed.

Generally, centrifuges are used throughout many manufacturing industries (Table 1), to separate suspended solids from liquid utilizing the centrifugal acceleration of the suspended particles directed outward from the axis of rotation. This force initiates the particle movement to the centrifuge periphery where it is trapped or contained by the wall of the rotating body. Alternatively, a density difference between two immiscible liquids is exploited to accelerate separation of the liquids (i.e. fat separation in dairies for cream or butter manufacture). A specialized use involves separation of water from fresh-cut vegetables before modified atmosphere packaging.

Much experience and information related to industrial-scale centrifugation exists within companies manufacturing the centrifugal machinery and these sources should not be overlooked when seeking information. Table 2 lists a representative selection of companies involved in the manufacture of centrifuges and their Internet addresses current at the time of writing. The Internet itself should not be overlooked as a source of information: simply typing the word 'centrifuges' in the request space of one search engine provided over 25 000 items for perusal.

Centrifugation is treated as a separation unit operation in chemical engineering and the article in Dahlstrom *et al.* (1997) by Leung on centrifuges should be consulted for an engineering perspective (see Further Reading). For a comprehensive treatment of industrial centrifugation technology, Leung's book on industrial centrifugation technology should be consulted.

Over the past 10–15 years the growing uses for centrifuges industrially has resulted in a plethora of special centrifuges designed and adapted to particular uses. However, the machines may, in general, be characterized according to the classification of Table 3. Centrifuges fall into two general classifications, termed sedimentation centrifuges and filter centrifuges. In sedimentation centrifuges, solids are transported to the periphery wall of the rotating machine bowl and collected against this surface; liquid is removed from the solids by the close packing of the individual particulates. In filter centrifuges the solids are transported to the surface of a filter element and the solids trapped on this filter, while the liquid drains through the particulates and exits through the filter surface. The mechanism of solids drying is thus quite different between the two types of machine and the types of material each would be expected to treat most efficiently also differ considerably. The other important parameter is whether or not the machines are fed continuously or in batch mode. Generally, batch-mode machines are often considered obsolete for large scale separations, with the important exceptions of the continuing use of batch-mode basket centrifuges for the last recovery stages for white sugar and in the fresh-cut vegetable industry. Other exceptions also exist.

The approximate capabilities of several centrifuge types are indicated in Figure 1. The list is not exhaustive but examples of most types of centrifuge,

of developing (Figure 1). Particles sediment in the centrifugal field at a rate which increases with the centrifugal speed, increased particle size, increased density difference between liquid and solid phases, increased centrifuge radius and decreased fluid viscosity. The physical size, shape, design and construction of the centrifuge, in part, determine machine performance, but other factors affecting the properties of the feedstock are also important. Good separations of solid and liquid usually equate to high sedimentation velocity since large scale separations are usually carried out in a production plant where time is important, or in continuous-flow equipment where sedimentation velocity affects throughput rates.

Machine performance criteria are usually dependent on the purpose of centrifugation and can be measured by the purity of the separated liquid phase or the completeness of the removal of the solid phase. Performance may also be measured by several other criteria, some of which are listed in Table 4. A particularly effective method of enhancing separation performance is through increasing the diameter of the particles sedimented. This can be done by careful selection of conditions or addition of coagulants or flocculants. The purpose of coagulation or flocculation is to destabilize particles, inducing them to come together and agglomerate to form larger aggregates. This can be accomplished by modifying the surface charge characteristics, by modifying the hydrophobic/hydrophilic character of the particles, or by using surfactants to reduce water-binding characteristics. Alternatively, charge repulsion by individual particles is reduced by adding polyvalent cations such as aluminium or ferric ions. The materials and methods used to effect flocculation/coagulation are listed in Table 5. A wide array of commercially available materials are marketed carrying a wide range of molecular sizes. The flocculant/coagulant choice can be partially made on the basis of chemical knowledge of the particles to be sedimented, but the flocculant manufacturer's recommendations should also be considered in combination with empirical screening tests. Flocculant manufacturers can be particularly useful sources of information and again the Internet should not be overlooked as a source.

Sedimentation velocity is particularly important for continuous centrifuges where rapid sedimentation increases separation efficiencies and machine capacities. Particle removal from sewage particularly makes use of flocculant technology. Flocculant usage in food-processing applications is severely restricted because of health and safety regulations, and the need to provide food to consumers as free of additives as

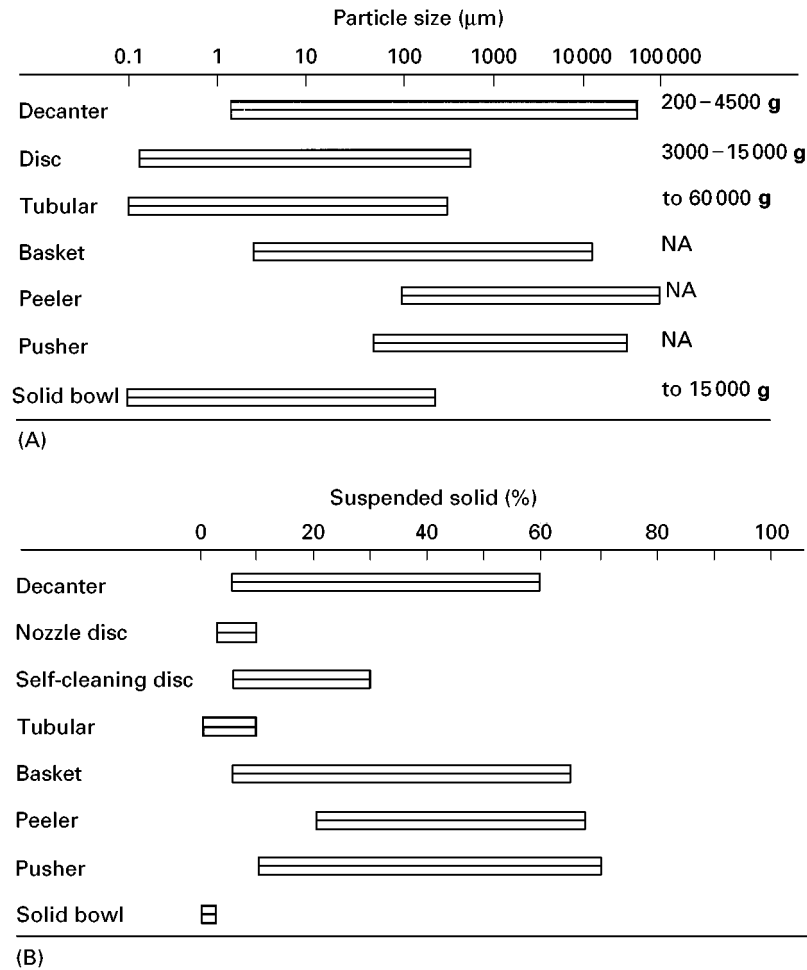

Figure 1 (A) and (B) Approximate capabilities of various centrifuge forms to sediment/separate particles and levels of suspended solids applicable. possible limits the acceptable flocculants. Downstream processing of fermentation broths or biotechnologically derived natural products for removal of particulate from a liquid stream provides another application of these flocculant materials. When used prior to unit operations such as chromatography or adsorption, these materials can help provide a clean, particle-free feed which will not block the columns

and adsorbent beds used for these purposes. Increasing the density difference between the liquid and solid phases is possible in certain applications by dilution prior to centrifugation if this is compatible with subsequent manufacturing steps, or by treatment with enzymes to hydrolyse viscous polymers and create denser core particles, which are more easily deposited. Apple juice manufacture by centrifugal means makes use of this latter mechanism. In this case, particle density is increased and the viscosity of the suspending liquid is reduced, both facilitating particle sedimentation. Another way of reducing the viscosity of the suspending liquid is to increase temperature. Increasing temperature decreases viscosity exponentially, improving sedimentation rates, thus sedimentation should be carried out at the highest temperatures compatible with preservation of any desirable properties of the material separated (supernatant or particulate), and the economics of the process being considered.

Decanter Centrifuges

A schematic diagram of a solid bowl decanter is shown in **Figure 2**. The machine consists of a horizontally oriented cylindrical bowl with one end tapered to form a cone. Within this cylindrical/conical section is a conveying scroll, with the same profile as the cylindrical/conical bowl. This scroll is rotated at a slightly different speed from the bowl through a gear system or via a separate drive. This arrangement fixes the differential speed, allows adjustment during operation, or accommodates automatic systems. Either method ensures that the scroll turns fast enough to avoid blockage by the solids which accumulate on the scroll faces, while allowing maximum solids retention times for good separations and dry ejecta. An automatic system allows the scroll speed to be adjusted to optimize the differential

speeds under operating conditions. The length of the cylindrical and conical sections and the conical angle may be varied, as can the scroll design, to accommodate diverse requirements of feedstock to achieve solids separations. Slurry to be separated is fed continuously through the centre pipe to be distributed evenly near the level of the conical taper and is accelerated to bowl speed. During acceleration, high shear forces are generated and this may result in considerable foam generation in some slurries such as food materials which contain protein or pectin capable of retaining air in suspension.

The depth of the liquid pool rotating against the bowl wall is determined by the positioning of the fluid discharge ports, dams or pick-up tubes. Solids settle through this pool to the bowl wall and are conveyed to the outlet ports at the distal conical end where they are ejected. The solids undergo a drying effect as they are dragged along the bowl wall and elevated to the exit ports as liquid drains back to the pool. Given the decanter configuration, there are four parameters which can be varied: scroll/bowl differential speed, pool depth, bowl rotational speed and feed rate. Fluid or supernatant is conveyed countercurrent to the solids, following the path of the scroll flights, to exit at a discharge port at the end of the cylindrical section. Centrifugal force can vary to over 4000 g depending on application and centrifuge.

The decanter's particular advantage is that it provides continuous separation of a wide variety of feedstocks with a broad range of solids concentrations. It is possible to configure a decanter to process feedstocks containing an aqueous phase, an oil phase and suspended solids, separating the three phases in the same machine. These machines are sometimes termed tricanter (**Table 3**) because of the three phase separations possible. Thus the decanter can be used to separate solid-liquid two-phase systems or solid-aqueous-oily three-phase systems. Separation

Figure 2 Schematic diagram of a decanter (scroll-bowl) centrifuge showing the major parts and indicating mode of operation. Reproduced with permission from Westfalia Separator AG, Oelde, Germany.

of two immiscible liquid phases is possible but is normally done in a disc-stack centrifuge specially designed for this purpose (i.e. cream separator). In the solid-liquid mode of operation, the ability to handle high solids content feed streams continuously, effectively and efficiently has made dewatering of municipal and industrial sewage a major use for decanter centrifuges. For similar reasons these machines have been used extensively for dewatering fine coal and for separation of mineral slurries in the mining and mineral-processing industries.

Decanters capable of separating three phases have been used to refine vegetable oils from complex feedstocks such as coconut, producing fat, milk and grated coconut solid fractions, recovery of animal fat from rendering operations and recovery of waste oil in petroleum refining. Watery oil derived from tank bottoms or trapped in containment lagoons which contain suspended solids may have this oil recovered using these machines. In each case value is added through the recovery of the oil phase as a saleable product. More recently, two-phase decanters have been adapted to replace presses in the extraction and further processing of a wide variety of fruit and vegetable juices. Separation in a tricanter of commercially exotic fruits such as sea buckthorn into pulp oil, juice and seed-enriched solid ejecta provides a potential future use of centrifugal technology. New, innovative uses for this versatile machine are still emerging.

The disadvantage of the machine is its inability to clarify liquid streams completely, as some suspended solids remain in the emerging stream. If complete clarity is required, another clarifying method must be used following decanter centrifugation. This may include equipment such as a disc centrifuge (clarifier) or filter system. For example, processes described for the extraction of fruit juices with a decanter replacing the press often have a clarifying disc stack centrifuge in the line following the decanter to provide the final solids removal and provide the brilliant clarity desired in many juice products. Alternatively, the clarifying centrifuge can be operated in such a way as to remove the particles larger than $0.5\ \mu\text{m}$ diameter to provide a stable juice opalescence.

Disc Stack Centrifuges

Originally designed as cream separators, these machines have achieved a high degree of sophistication and today represent a versatile group of centrifuges capable of achieving very high g factors, commonly ranging from 3000 to 15 000. The original application of cream separation is still performed as a specialized function in dairies where these machines

Figure 3 Bowl section of a self-cleaning disc stack centrifuge indicating direction of fluid flow and ejection of sedimented solids through passages controlled with hydraulically operated pistons. Discharge is intermittent. Nozzle machines allow for continuous discharge of solids through throttled nozzles while solid bowl machines without solid discharge mechanisms require manual cleaning from time to time depending upon feedstock solids. 1, Feed; 2, discharge; 3, photocell; 4, discs; 5, sediment holding space; 6, solids ejection ports; 7, operating water valve; 8, drain hole; 9, opening chamber; 10, closing chamber; 11, annular piston; 12, timing unit; 13, discharge pump. are also used for milk clarification and bacterial removal prior to high temperature-short time pasteurization. The disc stack centrifuge is a vertical-axis machine consisting of a series of conical spacers stacked within the centrifuge rotor (Figure 3). The centrifuge is arranged to allow continuous flow of feedstock into the lower part of the bowl. Fluid flows up through the channels formed by the stacked conical elements and particulates are sedimented to contact the inclined surface of a conical element. The particulates on the conical element are forced downward and outward until they underflow the cone to collect on the bowl wall. The effect of the angled conical element is to shorten the distance required for particle migration to a surface and reduce the turbulence produced by material flows within the centrifuge, resulting in rapid and complete clarification of the fluid stream. The number and spacing of the conical elements are important factors in the separation process.

These centrifuge types are for processing feedstocks with relatively low suspended solids in a feedstock requiring a high degree of clarification. They are also of use in situations requiring separation of two immiscible liquids – the separation of cream from milk is the most common example. However, extraction of biochemicals from aqueous substrates often makes

use of water-immiscible organic solvents and rapid separation of the two phases can be achieved in these machines. Removal/isolation of culture-grown bacterial or other cell is a useful function in the biochemical industries. In any role, consideration should be given to the need to seal the centrifuge against the dispersion of aerosols which may contain dangerous biochemicals, nonaqueous vapours or bacterial cells which may be toxic, flammable or explosive. Flushing with an inert gas such as nitrogen or carbon dioxide to avoid oxidation, and the need for temperature control of the centrifuge, feedstock and products should also be considered.

Disc stack centrifuges come in three basic configurations. In one configuration the sedimented solids are continuously ejected through carefully sized nozzles at the bowl periphery (nozzle discharge), allowing continuous operation of the machine with continuous discharge of solids. However, the degree of compaction of the solids is limited by the need to be free-flowing, and solids exit as a concentrate (~50%). In the second configuration, the bowl is equipped with the means to open a port at the periphery of the rotating bowl. This opening may be closed with a slide or piston which is hydraulically opened

according to a pre-set programme. The programme may be set by time or the centrifuge may be equipped with a monitoring device on the fluid exit side which monitors the light-scattering capability of the clarified output. Above set limits clarity deterioration triggers solid discharge. The centrifuge illustrated in Figure 3 is of this self-cleaning type. The third configuration is a solid-wall bowl which is primarily used for separation of liquid mixtures containing little or no solids. The bowl is cleaned manually, or with automatic removal machinery which requires process interruption, so it is advantageous for the sedimented solids content to be low since the machine operates in batch mode and machine capacity will be a function of the clean-out rate.

Solid Bowl and Tubular Centrifuges

Other batch-operated sedimenting centrifuges are the tubular centrifuge and the solid open-bowl centrifuge (without discs: Table 3 and Figure 4). Both machines are batch-operated because they do not incorporate the means for continually removing sedimented solids. The tubular centrifuge is configured with a long, small diameter tube capable of rapid rotation

Figure 4 Solid-bowl separator for separating and collecting fine suspended solids in a liquid stream. 1, Product feed; 2, product discharge; 3, bowl insert; 4, removable liner; 5, coolant discharge (bowl); 6, coolant feed (bowl); 7, coolant feed and 8, coolant discharge (upper section of frame); 9, removable liner; 10, coolant discharge and 11, coolant feed (hood); 12, centripetal pump. and generating very high *g* forces to above 40 000 *g*, whereas the solid-bowl/chamber-bowl machines carry a larger diameter bowl and operate in the 5000–10 000 *g* range. The solid-bowl machines are often equipped with a removable liner to facilitate solid removal and centrifuge cleaning, to reduce down time between batches. The narrow tube means that the solid-retaining capacity of the tubular centrifuge is small but the high *g* force makes the machine useful for collecting small particulate or cell debris in biotechnological applications. They are particularly useful for collecting a valuable particulate present at low concentration which requires high relative centrifugal forces for its isolation. Final cleaning of a fluid stream is another application, particularly for the solid-bowl machine, if the solid to be removed is of a refractory type, which would impose extensive wear on the nozzles or solid ejection ports of a disc stack machine or where high compaction of the solids is of value. This latter condition can be very desirable for biotechnological applications where isolation of expensive precipitates is a key function.

Hydrocyclones

This device is particularly unique as it separates solids and liquids by centrifugal principles, but contains no moving parts. The principle of the machine is illustrated in Figure 5. The slurry or fluid to be separated is pumped at high speed and enters the conically shaped machine tangentially. The conical shape causes the flowing liquid to swirl or rotate within the cone, with the result that suspended solids move to the wall while clarified liquid remains in the centre of the cone. This clarified liquid is drawn off at the top of the cone while the separated solids move to the bottom of the chamber for removal. The degree of separation is generally coarse; however, hydrocyclones find use in applications such as removal of sand or grit from fruit mash streams intended for juice extraction, to protect expensive equipment such as decanter scrolls or disc stack deslugging mechanisms from premature wear. They find use in pulp mills for paper fibre removal from liquid streams. These units are used extensively to remove particles from gas streams such as flue gases and as a particle collection mechanism for spray driers used in the production of food powders of various kinds. While the medium of drying and particle conveyance is air, and the prefix 'hydro' does not strictly apply, the principle is the same. Hydrocyclones may precede in line with filtering centrifuges since they can be used to concentrate the centrifuge feed and increase the efficiency of the basket or filter centrifuge.

Figure 5 Schematic diagram of a hydrocyclone. 1, Feed; 2, apex nozzle; 3, grit pot; 4, outlet, solids; 5, valve; 6, discharge, clarified liquid. Reproduced with permission from Westfalia Separator AG, Oelde, Germany.

Filter Centrifuges

These machines are characterized by sedimenting particulate on to a screen which may consist of slots, holes, a porous membrane, or filter cloth, where the solids are retained while the liquid portion flows through the screen to be carried away (Figure 6). Generally, the solids should be free-draining and at least 100–200 μm in diameter. These properties allow filter centrifuges to handle high solid concentrations in the input stream (Figure 1b: basket, peeler, pusher). It is of advantage to feed the machine with a feedstock of high solid concentration, since this promotes frequent machine cycling. Solid concentrations can be enhanced by using hydrocyclones or

Figure 6 Vertical basket centrifuge with pneumatic top discharge. Reproduced with permission from Krauss Mofferi, Munich, Germany.

settling tanks as pretreatment concentrators. The revolving bowl may be driven either from above or below the rotating parts. The cycle of a variable-speed basket centrifuge consists of acceleration to medium speed, slurry feed and even distribution over the retaining filter surface, and acceleration to operational speed to remove the liquid portion. At this higher speed the dewatered cake may be washed if the centrifuge is equipped with interior washing nozzles, and dewatered for the final time. The rotor speed is decreased and the solids removed, usually by mechanical means using a knife or plow to release the cake from the centrifuge wall. Solids are either dropped through the centrifuge bottom in a vertical axis machine, or gravity-fed down a chute in a horizontally mounted machine. Batch machines offer flexibility in centrifugal conditions, allowing adjustments for feed rates or feed solid concentration; however, they are not widely used except in the white sugar industry

since the higher throughput capacity makes continuous centrifuges more attractive.

Basket centrifuges can be made continuous by incorporating the means of removal of solids while the machine operates. Machines mounted horizontally utilizing a knife to peel the solids from within the centrifuge bowl are termed Peeler-type basket centrifuges (Table 3). In this configuration the knife enters the centrifuge and unloads the cake while the machine operates at full speed. This overcomes the requirement for speed management and permits shorter cycles and higher throughput capacities than simpler batch basket centrifuges. Vertical pneumatic conveying (Figure 6) is another possibility. Pusher centrifuges also fulfil this requirement for continuous operation. A double-stage pusher centrifuge is shown in Figure 7. Multiple-stage machines are available.

The centrifuge consists of a rotating perforated basket with an open end. Feed is through a rotating

Figure 7 A two-stage pusher-type centrifuge. Feed enters at (1) and is accelerated while passing over the cone (2) and distributed on the first-stage basket (3). The first-stage basket (4) hydraulically reciprocates under a static pusher plate (5), which advances the filter cake to the second-stage basket on the back stroke. The forward stroke of the first basket pushes the second basket cake off into the collecting chute (6). The means to wash the filter cake (7) and collect mother liquor or wash fluids (8) is usually provided. Reproduced with permission from White (1979).

hollow tube to a solid distribution device which distributes the slurry evenly on the basket during the back stroke of the hydraulically driven distributing plate. On the forward stroke the distributing plate exerts a pressure on the deposited cake, causing it to overflow the open end of the basket. If required, the deposited cake may be washed before the return stroke causes overflow of the solids. The screen/scroll centrifuge is also horizontally oriented, but the basket is conical-shaped and transport of the deposited, centrifugally dried slurry is accomplished by a scroll or scrapper blades in a manner reminiscent of the decanter scroll. The transported solids overflow the open end of the basket and are removed from the machine. The screen-bowl decanter is of similar design to the solid-bowl decanter discussed earlier except for the addition of a cylindrical screen behind the conical section of the bowl. The scroll spans the entire length of the bowl including the screen and conforms to the profile of the bowl and screen. Solids retained on the screen are scraped by the scroll to an exit beyond the screen. The purpose of the machine is to combine the solid sedimenting centrifuge with a screen centrifuge in an attempt to obtain a drier cake. Washing of retained solids may be effected in the first portion of the screen, while dewatering taking place in the second part. Decanters such as this

may provide serious competition to the peeler and pusher centrifuges by facilitating continuous separations in a more compact, mechanically simpler package.

A special application which is of growing importance in the food industry is the use of low speed basket centrifuges to dewater or dry fresh-cut vegetables, especially salad greens, for later use in modified atmosphere packages (**Figure 8**). These machines are usually of lighter construction than the heavy-duty machines described above, are batch-operated, and often have reusable rotating perforated baskets, to facilitate rapid unloading and reloading of the centrifuge. The reusable baskets are usually of light construction, often plastic, to allow easy manual handling and economic replacement. Such materials have low tolerance for acceleration and deceleration forces but are well suited for undemanding applications.

Summary

This article has provided an overview of the use of centrifuges in various industries. The ubiquitous nature of the machine throughout the industrial spectrum is apparent. It appears in heavy industrial uses such as sugar and oil refining and in light industrial

Figure 8 Small industrial-scale centrifuge for dewatering fresh-cut produce. The machine is operated in batch mode, but use of insertable plastic bowl minimizes down time between loads. Reproduced with permission from Freshline Machines, Sydney, Australia.

separations such as dewatering of vegetables. Performance demands also vary widely, ranging from high g applications required in isolating and manufacturing the diverse products of biotechnology to dewatering hundreds of tons of municipal sewage per day using machines of relatively low g capability. This is made possible by the wide variety of machines available. The recent application of decanters as press replacements in the fruit and vegetable juice industry required the independent development and widespread use of pectin-digesting enzymes (pectinases) for routine juice production. The reduction in viscosity

and release of dense core particles from the fruit mash which is characteristic of the action of these enzymes is a necessary precondition for the successful use of decanters. The fruit-processing industry is increasingly interested in the production of products from new, unconventional fruits and vegetables. An example is sea buckthorn, a fruit which consists of a seed, pulp and pulp oil, a three-phase system which might be separated into an oil stream, a stable opalescent juice and a seed containing pulpy ejecta in a single operation using a three-phase decanter. From these two examples drawn from the author's experiences in this industry it appears that future innovations are likely to be applications, which will in turn drive further refinement and development of the centrifugal machinery.

Macromolecular Interactions: Characterization by Analytical Ultracentrifugation

University of Queensland, Brisbane, Australia

Copyright © 2000 Academic Press

Analytical ultracentrifugation refers to the analysis of a macromolecular solution by its subjection to

gravitational forces up to 300 000-fold greater than gravity. From its inception by Svedberg in the mid-1920s, analytical ultracentrifugation has played a leading role in studies of macromolecular systems. One early success was its demonstration that proteins were polypeptides of discrete length rather than

polydisperse polymers of amino acid residues – the popular concept amongst colloid chemists at that time. This revolutionary finding was the seminal contribution that generated the present-day fields of protein chemistry and molecular biology. Indeed, for 40 years, the analytical ultracentrifuge was the primary source of information on the molecular mass and heterogeneity of proteins, as well as on the polydispersity of polymer preparations. At that stage, preparative ultracentrifugation, gel permeation (size exclusion) chromatography and gel electrophoresis were developed to take advantage of macromolecular separation on the basis of size and shape (as well as charge in some forms of gel electrophoresis). Meanwhile, the sedimentation equilibrium variant of analytical ultracentrifugation retained supremacy for many years as the benchmark standard of molecular mass measurement for a homogeneous protein – a role now being taken over by mass spectrometry. Furthermore, inroads into its status as the method of choice for determining molecular size distributions for polydisperse polymer preparations have now been made by light scattering as the means of analysing the column eluate in gel permeation chromatography. Nevertheless, such is the strength of analytical ultracentrifugation that it has survived those losses of traditional roles to become an invaluable tool for the characterization of reversible macromolecular interactions – a task which is beyond most of the techniques that have usurped its traditional roles.

Many proteins comprise a mixture of monomeric and polymeric states that coexist in rapid association equilibrium, whereupon the relative proportions of the two macromolecular states vary with total solute concentration in accordance with Le Chatelier's principle: the polymeric state is favoured by an increase in solute concentration whereas monomer is favoured by dilution. Analytical ultracentrifugation has great potential for characterizing the self-association equilibrium by virtue of these concentration-dependent changes in the average macromolecular state of the solute, and also for the characterization of rapid equilibria involving dissimilar reactants, for which similar considerations apply. The main emphasis in current analytical ultracentrifugation is thus the study of noncovalent macromolecular association equilibria: protein–protein interactions such as those involved in enzyme self-association or the binding of an antibody to its eliciting protein antigen; and protein–nucleic acid interactions such as those associated with regulation of the transcription of genetic information.

Sedimentation Velocity and Sedimentation Equilibrium

A complex in rapid association equilibrium with reactant species has no separate existence in the absence of the reactants. The characterization of such interactions requires methods that can accommodate the equilibrium coexistence of several species. This requirement is readily accommodated by either of the commonly used techniques in analytical ultracentrifugation – sedimentation velocity and sedimentation equilibrium. In the former, the centrifuge is operated at a sufficiently high angular velocity (speed) for the centrifugal force on a solute to dominate its migration. In sedimentation equilibrium the same instrument is operated at a much lower angular velocity to effect a balance between the radially outward flux of solute and the back-diffusional flow in response to the concentration gradient being generated. Before considering their application to the characterization of interacting systems, it is appropriate to describe the two techniques in relation to the information derived for a single noninteracting solute.

Measurement of a Sedimentation Coefficient

In sedimentation velocity, a solution is placed in a sector-shaped cell which allows unimpeded migration of solute molecules in a radially outward direction in response to the applied centrifugal field. At the commencement of the experiment, the solute concentration is uniform throughout the cell, but the application of a strong centrifugal field (typically 200 000–300 000 g operating at 50 000–60 000 rpm) leads to a progressive removal of solute from the inner region of the cell (**Figure 1**).

Migration of the resultant solute boundary is recorded optically and the sedimentation coefficient of the solute, s_A , is then determined from the rate of migration. Specifically:

$$s_A = (dr_p/dt)/\omega^2 r = (d \ln r_p/dt)/\omega^2 \quad [1]$$

where r_p denotes the radial position (cm) of the solute boundary after centrifugation at angular velocity ω (rad s⁻¹) for time t (s). Traditionally, the sedimentation coefficient has thus been determined from the slope ($\omega^2 s_A$) of the time dependence of $\ln r_p$. Despite being the rate of migration per unit field, s_A has the dimensions of time, but is usually reported in Svedberg units S (1 S = 10⁻¹³ s).

At the limit of zero solute concentration, the sedimentation coefficient, s_A^0 , is related to molecular

Figure 1 Schematic representation of migration in a sedimentation velocity experiment, showing the generation of a boundary between solvent and the solution subjected to centrifugation: r_p denotes the mean boundary position at time t_3 , and r_a the air–liquid meniscus (boundary position at zero time).

parameters by the expression:

$$s_A^0 = M_A(1 - \bar{v}_A\rho_s)/Nf_A \quad [2]$$

where f_A denotes the shape-dependent translational frictional coefficient of the solute with molecular mass M_A and partial specific volume \bar{v}_A ; ρ_s is the solvent density and N is Avogadro's number. Elimination of the frictional coefficient on the assumption of spherical geometry for the solute ($f_A = 6\pi\eta_s a_A$) leads to the relationship:

$$s_A^0 = M_A(1 - \bar{v}_A\rho_s)/(6\pi\eta_s a_A) \quad [3]$$

where η_s is the solvent density and a_A is the Stokes radius of the solute (radius of the equivalent hydrodynamic sphere). The sedimentation coefficient is thus a function of the size (shape) as well as the buoyant molecular mass, $M_A(1 - \bar{v}_A\rho_s)$, of the solute.

Experimental Aspects of Sedimentation Equilibrium

Unequivocal determination of the buoyant molecular mass by analytical ultracentrifugation is clearly conditional upon replacement of the frictional coefficient in eqn [2]. On the grounds that the translational diffusion coefficient, D_A^0 , is related to f_A by the expression:

$$D_A^0 = RT/(Nf_A) \quad [4]$$

where R and T refer to the universal gas constant and the absolute temperature (K), respectively,

the influence of f_A upon the separate magnitudes of the sedimentation and diffusion coefficients disappears from their ratio. Thus:

$$s_A^0/D_A^0 = M_A(1 - \bar{v}_A\rho_s)/(RT) \quad [5]$$

In sedimentation equilibrium, the solute distribution is governed by this ratio of s_A^0/D_A^0 . The parameter to emerge from the analysis of such distributions is the buoyant molecular mass of the solute, $M_A(1 - \bar{v}_A\rho_s)$. Its conversion to a molecular mass requires assignment of a magnitude to $(1 - \bar{v}_A\rho_s)$, which may be determined experimentally by density measurements and the relationship $(1 - \bar{v}_A\rho_s) \approx (\rho - \rho_s)/c_A$, where ρ is the density of a solute solution with weight concentration c_A .

Sedimentation equilibrium experiments are conducted in a double-sector cell. One sector contains the solution of macromolecular solute and the other the appropriate solvent, which for charged solutes is the buffer with which the solution of macro-ion is in dialysis equilibrium. As in sedimentation velocity, the solute concentration is initially uniform throughout the column of solution (Figure 2). Application of the centrifugal field then results in depletion of solute in the vicinity of the air–liquid meniscus (r_a) and its accumulation at the cell base (r_b). However, at the relatively low speeds of such experiments (say, 10 000 rpm for a 50 kDa protein), these tendencies are countered by back-diffusion in response to the concentration gradient being formed. The net result is a progression towards

Figure 2 Schematic representation of the approach to a time-independent distribution in a sedimentation equilibrium experiment: the initially uniform concentration gradually changes into an exponential distribution described by eqn [7] for a single solute.

a time-independent exponential increase in solute concentration across the cell (Figure 2).

Because the time taken to attain sedimentation equilibrium varies inversely with the square of the column length, columns longer than 3 mm are rarely used. Whereas 3–4 weeks of centrifugation would be required to attain time independence of the solute distribution in a completely filled cell ($r_b - r_a \approx 1$ cm), effective sedimentation equilibrium can be reached within 16–36 h by decreasing the column length to 2–3 mm.

In the original treatise on analytical ultracentrifugation published by Svedberg and Pedersen in 1940, sedimentation equilibrium was considered in terms of the balance between the processes of sedimentation and diffusion. However, later consideration led to the realization that results from such experiments were amenable to rigorous thermodynamic analysis by expressing the diffusional flow in terms of the negative gradient of solute chemical potential. Consequently, even though the experimental record is in terms of solute concentration as a function of radial distance, the distribution of a single solute at sedimentation equilibrium is defined in terms of its thermodynamic activity:

$$z_A(r) = z_A(r_F) \exp[M_A(1 - \bar{v}_A \rho_s) \omega^2 (r^2 - r_F^2) / (2RT)] \quad [6]$$

which relates the thermodynamic activity of solute at any given radius, $z_A(r)$, to that at a chosen reference radial position, r_F . Although procedures have now been devised which make allowance for effects of thermodynamic nonideality, the situation is simplified for the present purpose by restricting consideration to ideal systems in which the two thermodynamic activities may be replaced by concentrations $c_A(r)$ and $c_A(r_F)$: eqn [6] thus becomes:

$$c_A(r) = c_A(r_F) \exp[M_A(1 - \bar{v}_A \rho_s) \omega^2 (r^2 - r_F^2) / (2RT)] \quad [7]$$

From the logarithmic form of eqn [7] namely:

$$\ln c_A(r) = \ln c_A(r_F) + M_A(1 - \bar{v}_A \rho_s) \omega^2 (r^2 - r_F^2) / (2RT) \quad [8]$$

it is evident that:

$$M_A(1 - \bar{v}_A \rho_s) = (2RT/\omega^2) d[\ln c_A(r)]/dr^2 \quad [9]$$

which allows an unequivocal estimate of the buoyant molecular mass to be obtained from the slope of $\ln c_A(r)$ versus the square of radial distance.

Ultracentrifuge Studies of Solute Self-association

The use of analytical ultracentrifugation in protein chemistry for molecular mass determination is now usually bypassed in favour of its calculation from the amino acid sequence or its measurement by mass spectrometry. However, because such molecular mass values refer only to the covalently linked polypeptides chain(s), they provide no information about the macromolecular state of the functional protein or enzyme. In the simplest current application of sedimentation equilibrium, molecular mass measurement is sometimes used to elucidate the nature of quaternary structure, which is an example of a self-association equilibrium displaced completely in favour of the polymeric state.

The aim of this section is to outline the basic principles of the use of analytical ultracentrifugation for the characterization of reversibly associating systems. Although more elaborate and intricate procedures are employed in practice, their description is beyond the scope of this introduction to the topic.

Characterization of Solute Self-association by Sedimentation Velocity

Because of the concentration-dependent variation in the average macromolecular state of a self-associating solute, the best approach in sedimentation velocity studies is to determine the dependence of the weight-average sedimentation coefficient, \bar{s}_A , upon total solute concentration, \bar{c}_A . Procedural details for the measurement of \bar{s}_A are as described above (eqn [1]), except that the asymmetric shape of the single reaction boundary that forms between solvent and the plateau region with concentration \bar{c}_A (Figure 1) necessitates the location of the boundary position, \bar{r}_p , as the square root of the second moment:

$$\bar{r}_p^2 = \left[\int_0^{\bar{c}_A} r^2 d\bar{c}_A \right] / \bar{c}_A \quad [10]$$

to make allowance for the effects of migration in a sector-shaped cell rather than one with uniform cross-sectional area.

For a two-state self-association involving monomer (species 1) and dimer (species 2) the weight-average sedimentation coefficient is given by the expression:

$$\bar{s}_A = \alpha_1 s_1 + (1 - \alpha_1) s_2 \quad [11]$$

where $\alpha_1 = c_1/\bar{c}_A$ is the weight fraction of monomer, and where the sedimentation coefficient of

Figure 3 Studies of solute self-association by sedimentation velocity: (A) Concentration dependence of the weight-average sedimentation coefficient simulated (eqn [10]) for a monomer–dimer system where $K_2 = 3.5 \text{ L g}^{-1}$, $s_1 = 2.4 \text{ S}$ and $s_2 = 3.8 \text{ S}$. (B) Analysis of the data for the determination of K_2 by means of eqn [13].

monomer, s_1 , may be obtained by extrapolation of \bar{s}_A to zero solute concentration (Figure 3A). However, the evaluation of α_1 from eqn [11] also depends upon knowledge of s_2 , the sedimentation coefficient of dimer, which is not readily obtained experimentally. An estimate is therefore usually made on the basis of the relationship $s_2 = s_1(2^{2/3})$, which follows from eqn [3] and assumed spherical geometry for monomeric and dimeric species. Knowledge of s_2 then allows evaluation of the weight fraction of monomer from the following rearrangement of eqn [11]:

$$\alpha_1 = (s_2 - \bar{s}_A)/(s_2 - s_1) \quad [12]$$

whereupon the dimerization constant, $K_2 = (1 - \alpha_1)\bar{c}_A/(\alpha_1\bar{c}_A)^2$, may be determined.

Application of this approach to the data in Figure 3A, which have been simulated for a system with $s_1 = 2.4 \text{ S}$, $s_2 = 3.8 \text{ S}$ and $K_2 = 3.5 \text{ L g}^{-1}$, is illustrated in Figure 3B. From the logarithmic form of the expression for the dimerization constant ($K_2 = c_2/c_1^2$), namely:

$$\log[(1 - \alpha_1)\bar{c}_A] = \log K_2 + 2 \log(\alpha_1\bar{c}_A) \quad [13]$$

in present terminology, K_2 may be obtained as the ordinate intercept of the linear dependence of $\log[(1 - \alpha_1)\bar{c}_A]$ versus $\log(\alpha_1\bar{c}_A)$; this has a mandatory slope of 2 for a monomer–dimer equilibrium.

Characterization of Solute Self-association by Sedimentation Equilibrium

The above approach can be applied to the dependence of weight-average molecular mass \bar{M}_A upon total solute concentration \bar{c}_A by substituting molecular masses for the corresponding sedimentation coefficients in eqn [12]. Furthermore, there is no ambiguity about the magnitude of M_2 , which is twice the value of \bar{M}_A in the limit of zero solute concentration. Although this was indeed the original procedure used for characterizing solute self-association by sedimentation equilibrium, it has been superseded by a more accurate method involving direct analysis of the sedimentation equilibrium distribution(s).

Figure 4A presents simulated sedimentation equilibrium distributions at 15 000 and 25 000 rpm for a reversibly dimerizing protein with a buoyant molecular mass of 6.5 kDa for monomer ($M_1 \approx 25 \text{ kDa}$) and an equilibrium constant of 3.5 L g^{-1} . Because the

Figure 4 Studies of solute self-association by sedimentation equilibrium. (A) Simulated concentration distributions reflecting reversible dimerization of a monomer ($M_1 = 25 \text{ kDa}$) governed by an association equilibrium constant of 3.5 L g^{-1} in sedimentation equilibrium experiments at 15 000 (▲) and 25 000 (△) rev min⁻¹. (B) Plot of data in readiness for global analysis according to eqn [15] with a fixed value of 0.4 g L^{-1} for the total solute concentration $\bar{c}_A(r_F)$ at reference radial position r_F .

distributions are at chemical equilibrium, the total solute concentration at each radial distance may be expressed in terms of monomer concentration by the relationship:

$$\bar{c}_A(r) = c_1(r) + K_2[c_1(r)]^2 \quad [14]$$

On the other hand, the condition of sedimentation equilibrium dictates that the distribution of monomer be described by eqn [7]. Combination of these two requirements leads to the expression:

$$\bar{c}_A(r) = c_1(r_F)\psi_1(r) + K_2[c_1(r)\psi_1(r)]^2 \quad [15]$$

$$\psi_1(r) = \exp[M_1(1 - \bar{v}_A\rho_s)\omega^2(r^2 - r_F^2)/(2RT)] \quad [16]$$

The application of this approach is illustrated in **Figure 4B**, where global analysis of the two distributions from **Figure 4A** has been effected on the basis of a common $\bar{c}_A(r_F)$ value of 0.4 g L^{-1} , thereby ensuring a common value of $c_1(r_F)$. Magnitudes of $\psi_1(r)$ at 20°C have then been calculated on the basis of the appropriate r_F value, the buoyant molecular mass of monomer and the angular velocity. In as much as $c_1(r_F)$ and K_2 are both constants, their magnitudes are obtained by nonlinear curve-fitting of the combined $[\bar{c}_A(r), \psi_1(r)]$ data sets to the above quadratic expression in $\psi_1(r)$.

Interactions Between Dissimilar Reactants

Although interactions between dissimilar reactants far outnumber those entailing solute self-association in biology, the study of ligand binding by analytical ultracentrifugation has received far less attention – a situation being remedied to some extent now.

Studies of Ligand Binding by Sedimentation Velocity

In considering the quantification of acceptor–ligand interactions by sedimentation velocity, there are two situations to examine: one in which a macromolecule (acceptor, A) reacts with a small molecule (ligand, B); and the situation in which both acceptor and ligand are macromolecular. In the former, provided that the ligand is sufficiently small for the acceptor–ligand complex AB (or complexes AB_i for ligand binding to multiple acceptor sites) to co-migrate with acceptor ($s_{AB} \cong s_A > s_B$), the free ligand concentration is readily determined by sedimentation velocity. As depicted schematically in **Figure 5A**, the subsection of an equilibrium mixture to a high centrifugal field under those circumstances generates a biphasic boundary pattern

Figure 5 Schematic representations of boundary patterns encountered in sedimentation velocity studies of ligand binding. (A) Direct evaluation of the free ligand concentration (C_B^β) for a system where acceptor and acceptor–ligand complex(es) co-migrate. (B) The corresponding situation when acceptor and ligand are both macromolecular ($s_{AB} > s_A > s_B$).

in which the concentration in the slower-migrating (β) phase reflects free ligand at its equilibrium concentration in the mixture (α phase) with total molar concentrations \bar{C}_A^α and \bar{C}_B^α of acceptor and ligand, respectively. Results obtained are thus akin to conventional ligand-binding data obtained by (say) equilibrium dialysis; and may therefore be treated in an analogous fashion.

In the second case in which the ligand is also macromolecular, the sedimentation coefficient of the AB complex is likely to be greater than that of either reactant ($s_{AB} > s_A > s_B$). Under those circumstances, a biphasic boundary pattern is again generated, but the slower-migrating phase corresponds to the reactant in molar excess: the situation represented in **Figure 5B** reflects a molar excess of ligand. Although the concentration of pure ligand in the slower-migrating phase (C_B^β) can be measured, it does not equal the free ligand concentration (C_B^α) in the equilibrium mixture. However for a 1:1 interaction, the free concentration of the other reactant may be

determined from the expression:

$$C_A^\alpha = (\bar{C}_A^\alpha - \bar{C}_B^\alpha + C_B^\beta)(s^{\alpha\beta} - s_B)/(s_A - s_B) \quad [17]$$

where C_i again denotes a molar concentration, and where $s^{\alpha\beta}$ is the sedimentation coefficient of the reaction boundary between the pure solute phase and that corresponding to the original mixture. Combination of the consequent value of C_A^α with the composition of the mixture (\bar{C}_A^α , \bar{C}_B^α) then yields the binding constant K_{AB} on the grounds that:

$$K_{AB} = C_{AB}^\alpha / (C_A^\alpha C_B^\alpha) = (\bar{C}_A^\alpha - C_A^\alpha) / [C_A^\alpha (\bar{C}_B^\alpha - \bar{C}_A^\alpha + C_A^\alpha)] \quad [18]$$

For purposes of simplification, the above quantitative treatments assume migration in a rectangular cell under the influence of a homogeneous field. Sedimentation in a sector-shaped cell leads to radial dilution that slightly decreases the magnitudes of the various concentrations. However, the uncertainties inherent in the measurements of C_B^β and the various differences in sedimentation coefficients are usually sufficient to justify the approximations involved in such interpretation of sedimentation velocity patterns.

Studies of Ligand Binding by Sedimentation Equilibrium

For a reversible interacting between an acceptor A and a ligand B , there are only two independent sedimentation equilibrium distributions – one for the acceptor constituent which includes the acceptor contribution to AB complex(es) as well as free reactant; and the corresponding distribution for the ligand constituent. Thus:

$$\bar{C}_A(r) = C_A(r) + K_{AB}C_A(r)C_B(r) + \dots \quad [19]$$

$$\bar{C}_B(r) = C_B(r) + K_{AB}C_A(r)C_B(r) + \dots \quad [20]$$

Figure 6 presents sedimentation equilibrium distributions for the individual species in centrifugation of a 1 : 1 interacting system with $M_A(1 - \bar{v}_A\rho_s) = 12$ kDa, $M_B(1 - \bar{v}_B\rho_s) = 3$ kDa and $K_{AB} = 50\,000$ mol L⁻¹ at 15 000 rpm. Also shown are the constituent distributions.

Substituting the condition of sedimentation equilibrium (eqn [7]) for the individual reactants into the above expressions allows them to be rewritten in the form:

$$\bar{C}_A(r) = C_A(r_F)\psi_A(r) + K_{AB}C_A(r_F)C_B(r_F)\psi_A(r)\psi_B(r) + \dots \quad [21]$$

$$\bar{C}_B(r) = C_B(r_F)\psi_B(r) + K_{AB}C_A(r_F)C_B(r_F)\psi_A(r)\psi_B(r) + \dots \quad [22]$$

Figure 6 Simulated sedimentation equilibrium distributions for the individual species (---) resulting from centrifugation at 15 000 rpm of a mixture of acceptor with $M_A(1 - \bar{v}_A\rho_s) = 12$ kDa and ligand with $M_B(1 - \bar{v}_B\rho_s) = 3$ kDa undergoing reversible 1 : 1 interaction governed by a binding constant of $50\,000$ mol L⁻¹. The solid curves describe distributions in terms of the total concentrations of the separate constituents (\bar{C}_A , \bar{C}_B).

Furthermore, because $\psi_A(r) = [\psi_B(r)]^u$ where $u = [M_A(1 - \bar{v}_A\rho_s)]/[M_B(1 - \bar{v}_B\rho_s)]$, these expressions become discrete polynomials in terms of $\psi_B(r)$ and the constant parameters $C_A(r_F)$, $C_B(r_F)$ and K_{AB} . The problem of evaluating K_{AB} thus amounts to nonlinear regression analysis of the $[C_i, \psi_B(r)]$ distributions to obtain the three constants as curve-fitting parameters.

The extent to which advantage may be taken of this approach clearly depends upon the nature and number of sedimentation equilibrium distributions available for analysis. In that regard, the maximum potential for quantitative analysis pertains to the situation in which the optical system provides information on the separate concentrations of acceptor and ligand constituents. However, the optical system may well only monitor one constituent, or it may yield a single distribution related to the combined constituent concentrations, $\bar{C}_A(r) + \bar{C}_B(r)$. The latter situations are clearly less than optimal from the viewpoint of characterizing the interactions, but procedures (admittedly less accurate) have been devised to illustrate the feasibility of a quantitative analysis, even under these adverse circumstances.

Future Developments

Despite the fact that the characterization of macromolecular interactions by analytical ultracentrifugation has attracted the attention of physical biochemists for the past 50 years, its application is only now filtering through to the general biochemical community. Inasmuch as the required methodology is

largely in place, the stage seems set for an exciting revitalization of analytical ultracentrifugation as the cell biologists begin to tackle the characterization of the myriads on interactions detected during the past few decades of qualitative research.

Introduction

Separation

Separation, as discussed here, is a mechanical means of the following:

- Separating immiscible liquids with different specific gravities (purification).
- Removing insoluble solids from a liquid (clarification if a liquid is the main product; dewatering if the solids are the chief product).
- Removing excess liquid from insoluble solids (thickening with the solids slurry in a more viscous form being the product).
- Some intermediate combination (degripping – removal of oversize particles; desliming – removal of fine particles; or some other form of classification – splitting the slurry into two generally liquid components with the solids being split based on particle size and/or density).

Centrifuges

Centrifuges are usually divided into two types, sedimenting and filtering. Sedimenting centrifuges are characterized by a solid bowl wall and include tubular bowl (Figure 1), disc stack (Figure 2) decanter (Figure 3) and imperforate basket centrifuges. Filtering centrifuges have perforated bowl walls, which support screens or cloth or both and include perforate basket centrifuges, peelers and pushers.

The ultracentrifuge and the gas centrifuge represent special cases that establish separations based on gradients on a molecular scale and are not included in this discussion.

Although centrifuges have been applied industrially for well over a century, centrifuge theory is not well developed. Centrifuges are not designed for specific applications using fundamental principles. Any discussion of centrifuge theory must also define the limitation of the theory. The best means of predicting the performance that will be obtained by processing a material through a centrifuge is to actually process the material through a centrifuge.

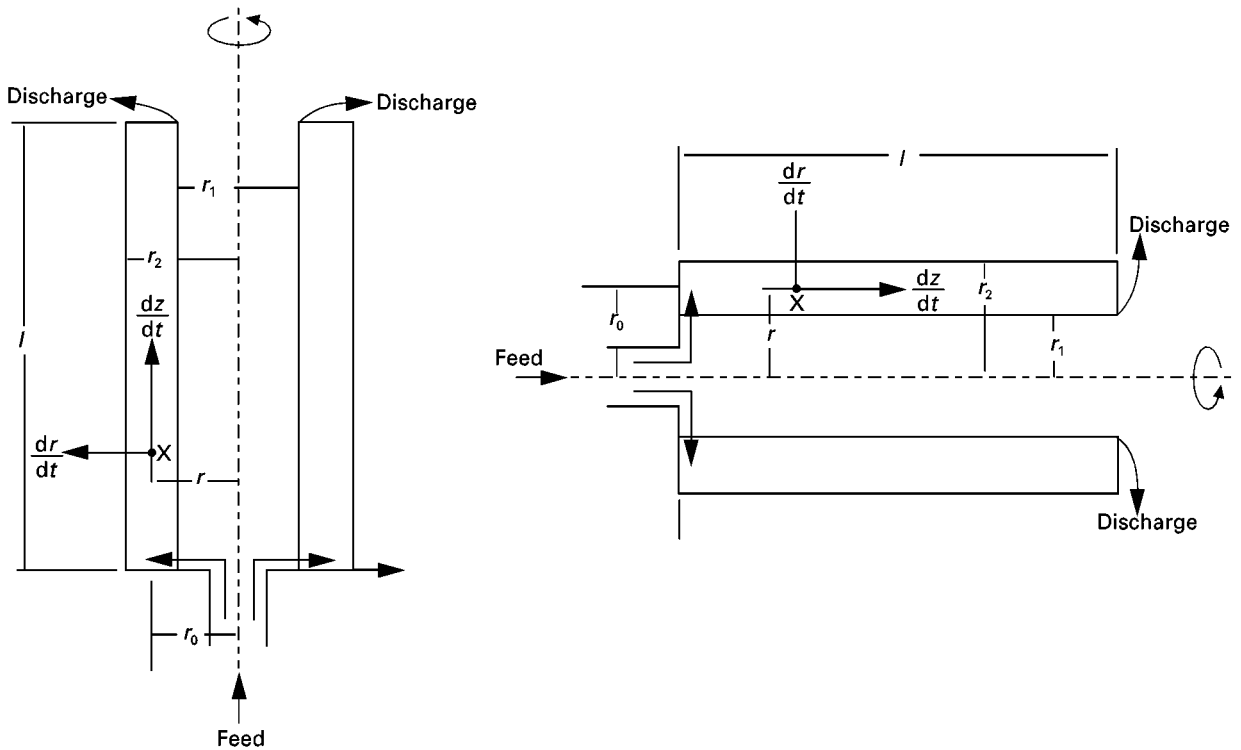

Figure 1 Tubular bowl (X represents the initial position). Centrifugal field is high enough that separating capacity of bowl is considered the same when rotating vertically or horizontally. Same sigma formula applies to tubular bowl, decanter and imperforate basket.

G-level

The fundamental characteristic of all centrifuges is that they contain a rotor that spins. A centrifugal field is used to augment separation. The magnitude of the enhancement is sometimes incorrectly described as the G-force. The relative centrifugal force (RCF) or G-level is not a force; it is a ratio, that of acceleration

of the centrifugal field to that of acceleration owing to the Earth's gravity. It has dimensionally no units:

$$G = \omega^2 r / g \left(\frac{1}{s^2} \times \text{cm} \right) / (\text{cm s}^{-2}) \quad [1]$$

This ratio may reach 60 000 on small laboratory units and 20 000 on small industrial scale units. This ratio tends to decrease as the size of the rotor increases. The ratio is normally large enough that a rotor rotating horizontally is considered to have the same separating capacity that it would have if it rotated

Figure 2 Disc centrifuge (X represents the initial position).

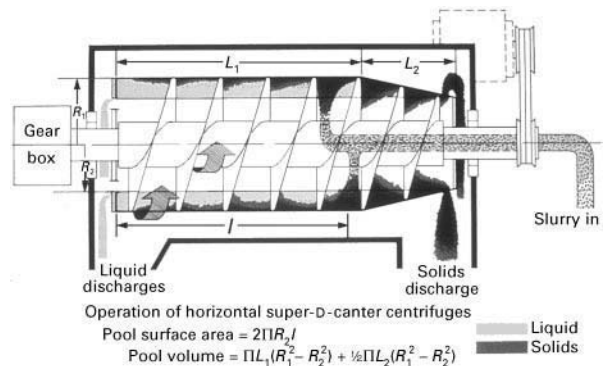

Figure 3 Decanter.

vertically, i.e. the influence of the Earth's gravitational field is negligible while the rotor is spinning.

Performance

Since centrifuges typically remove solids from one or more liquid streams, some measure of how well this is being performed is usually desirable. The recovery, sometimes (especially in the case of filtering centrifuges) referred to as yield, is defined as:

Recovery (%)

$$= \frac{\text{Collected insoluble solids}}{\text{Feed insoluble solids}} \times 100 \quad [2]$$

$$= \frac{\text{Cake insolubles (\%)} \times \text{Cake rate}}{\text{Feed insolubles (\%)} \times \text{Feed rate}} \times 100 \quad [3]$$

$$= \frac{cC}{fF} \times 100 \quad [4]$$

As a practical matter, cake rates are difficult to measure. This can be addressed by manipulating mass balances. Recovery can be defined in terms of insoluble (suspended) solids concentrations, which may be more accurately determined than cake rates.

The liquids balance:

$$F = C + E \quad [5]$$

or:

$$E = F - C \quad [6]$$

The solids balance:

$$fF = cC + eE \quad [7]$$

By substitution:

$$fF = cC + e(F - C) \quad [8]$$

$$= cC + eF - eC \quad [9]$$

$$F(f - e) = C(c - e) \quad [10]$$

$$C/F = (f - e)/(c - e) \quad [11]$$

$$\text{Recovery (\%)} = (c/f)((f - e)/(c - e)) \times 100 \quad [12]$$

Recovery then is also a function of feed solids concentration. Effluent quality is not the sole measure of recovery. High solids concentration in the effluent may simply mean that the feed solids are high. Conversely, lack of solids in the effluent may simply mean lack of solids in the feed, not a high level of recovery.

The use of overall percentage recovery may not be adequate to compare dissimilar centrifuges, especially

those on applications such as classification when recovery levels are kept low.

Centrifuges may have the effect of altering the particle-size distribution. Two different types of centrifuges, even if operating at the same overall recovery level, may split a slurry into components having significantly different particle-size distributions.

Sedimenting Centrifuges

Ideal System

Newton and Stokes have promulgated the laws describing the movement of particles. When a force is applied to a particle it is accelerated:

$$F = ma \quad [13]$$

In a static settling tank under the influence of the Earth's gravity, the particle settles along the radius of the earth. When g is the gravitational constant:

$$F = mg \quad [14]$$

In a centrifugal field, the acceleration, $\omega^2 r$, results in a force that acts normal to the axis of rotation (Figure 4):

$$F = m\omega^2 r \quad [15]$$

In a sedimenting centrifuge, a continuous liquid phase moves through the rotor. In order to accomplish a useful separation, the discontinuous phase – either the insoluble solids or immiscible liquids drops (or both) – must move in a direction different from the flow of the continuous liquid. Stokes' law is usually applied to describe the relationship. The effective force accelerating the particle in a centrifugal field is then described:

$$F_p = (m_p - m_1)\omega^2 r \quad [16]$$

where m_p is the mass of the particle and m_1 is the mass of the liquid displaced by the particle. If we define $\Delta\rho = (\rho_p - \rho_l)$, the difference in the density between the particle and the continuous liquid phase, then for a spherical particle of diameter, D :

$$F_p = (\Pi/6)\Delta\rho D^3 \omega^2 r \quad [17]$$

If the diameter is small, or the viscosity is high, the particle moves at a velocity below the turbulent range and Stokes' law defines the force of the liquid phase

Defined as:

$$\frac{\omega^2 r}{g}$$

where :

ω is rotational velocity (rad s⁻¹)
 r is radius of rotation in inches
 g is gravitational constant
 (32.2 in s⁻²)

Figure 4 G-level.

resisting the particle as:

$$F_l = 3\pi\eta Dv_s \quad [18]$$

If the particle settles long enough (reaches equilibrium), then $F_l = F_p$ and, in a centrifugal field:

$$v_s = (\Delta\rho D^2 \omega^2 r) / 18\eta \quad [19]$$

In the Earth's gravitational field:

$$V_g = (\Delta\rho D^2 g) / 18\eta \quad [20]$$

The difference between the velocity in the centrifugal field and in the Earth's gravitational field is twofold. The first difference is that the velocity in the centrifugal field may be three to four orders of magnitude higher. The second is that the velocity in a centrifugal field depends on the distance from the centre of rotation, so that the velocity increases as the particle moves outward from the centre of rotation. In the Earth's gravitational field, the velocity is considered independent of position.

Sigma Value

The most widely used method of quantifying capacity in sedimenting centrifuges is the sigma value which was introduced by Ambler in the 1950s. Sigma is used as an index of centrifuge size and typically has units of cm².

The sigma concept attempts to isolate the process system factors effecting separation from the centrifuge factors effecting separation (Figure 1). The tubular bowl was the first centrifuge to which sigma is applied. The tubular bowl is a rotating cylinder in which feed is introduced through the bottom end cap. The continuous fluid flows through the rotor and overflows the top of the bowl. If the solid particles having a specific gravity higher than the liquid are successfully separated, they accumulate on the inside of the rotor and are removed batchwise by manually cleaning the bowl. If the distance settled (x) is small, the velocity is constant, eqn [19] then can be expanded:

$$x = v_s t = [(\Delta\rho D^2 \omega^2 r) / 18\eta] (V/Q) \quad [21]$$

If we consider an ideal system, half of the particles of diameter D would be removed when:

$$x = s/2 \quad [22]$$

$$Q = [(\Delta\rho D^2) / 9\eta] (V\omega^2 r/s) \quad [23]$$

or:

$$Q = 2v_s \Sigma \quad [24]$$

where v_s characterizes the process system:

$$v_s = (\Delta\rho D^2 g) / 9\eta \quad [25]$$

and Σ characterizes the centrifuge:

$$\Sigma = (V\omega^2 r_e) / g s_e \quad [26]$$

with r_e and s_e being the effective radius and effective settling distance in the centrifuge.

The problem then is to define r_e and s_e . If the liquid layer is not thin, Ambler considered that:

$$r_e/s_e = 1/\ln(2r_2^2/r_1^2) \quad [27]$$

Ambler maximized the approximation for the tubular bowl as:

$$\Sigma = (2\pi l \omega^2 / g) (\frac{3}{4} r_2^2 + \frac{1}{4} r_1^2) \quad [28]$$

Svarovsky and Vesilind each use slightly different approximations for the effective radius.

Records argues that a second derivation assuming that all particles start on the surface instead of uniformly distributed throughout the annular space yields:

$$\Sigma = (2\pi l \omega^2 / g) (\frac{1}{2} r_2^2 + \frac{1}{2} r_1^2) \quad [29]$$

Clearly as the depth of liquid decreases $r_1 \rightarrow r_2$, the values for both estimates of Σ become equal.

The equivalent area of a decanter and a gravity settling tank is shown in Figure 3 and Figure 5, respectively.

Figure 5 Gravity settling tank.

Sigma assumptions The assumptions can be divided as follows:

- **Stokes' law:** The particles or droplets are spherical and uniform in size. Settling of a particle is unhindered by the smaller particles ahead of it. The particles do not deaggregate, deflocculate, agglomerate, precipitate, dissolve, emulsify or flocculate. There is no change in viscosity or density (little or no temperature change).
- **Reynolds' number:** The value for the Reynolds' number, $(v_s \rho D)/\eta$, is less than one, so that the deviation from the Stokes settling velocity is relatively small.
- **Distribution:** The particles are evenly distributed in the continuous liquid phase. The feed is uniformly introduced into the full space available for its flow. The flow is streamlined. There is no displacement of flow of the continuous phase by the sedimented particle phase or the introduction of feed. There is no remixing of the continuous and discontinuous phases.

Sigma limitation: similarity of feed Since Σ is the index of the size of the centrifuge, traditionally the throughput (Q_1) of a centrifuge of a size (Σ_1) has been used to determine the throughput (Q_2) to a usually larger size (Σ_2) centrifuge. In the normal course of commerce, the performance of the test centrifuge with Σ_1 occurs at a time and place different from that in which the centrifuge with Σ_2 will operate. The small unit may be tested on lab batches, months or even years ahead of the construction of a full-scale plant. Eqn [24] can be restated as:

$$Q_1 = 2v_{s1}\Sigma_1 \quad [30]$$

and:

$$Q_2 = 2v_{s2}\Sigma_2. \quad [31]$$

It is important to remember that:

$$Q_2 = Q_1(\Sigma_2/\Sigma_1) \quad [32]$$

if and only if:

$$v_{s1} = v_{s2} \quad [33]$$

The process system parameters that allow v_{s1} must be duplicated to allow v_{s2} .

The feed stream and process system should be properly documented to ensure that the process system does not adversely effect the following properties described in eqn [25]:

$$v_s = (\Delta\rho D^2 g)/9\eta$$

It is generally assumed that increasing the sedimenting velocity (v_s) produces a better (more complete, faster, possibly more economical) separation. Therefore increasing v_s increases sedimentation capacity at constant Σ . Eqn [14] illustrates several important relationships:

- The larger the particle diameter, the greater the sedimentation rate.

Corollaries:

- A. Flocculation may enhance performance by increasing particle size.
 - B. Care should be taken in those process steps ahead of the centrifuge to limit particle-size degradation by either mechanical or biological means.
- The greater the difference in the density between the particle and the continuous phase, the greater the sedimentation rate.

Corollaries:

- A. Temperature is important. If the density differences are small, the percentage change in density of the continuous phase may be significant. The density of water is normally taken as unity, but actually changes by approximately 20% from 20°C to 30°C.
 - B. In certain systems, e.g. mineral oil and water, there may be no density difference at a given temperature, therefore separation would not be possible. Changing the temperature and thus the densities would make separation possible. In extreme cases, changing the temperature may invert the light and heavy immiscible phases.
- The lower the viscosity of the continuous phase, the greater the sedimentation rate.

Corollaries:

- A. Again, temperature is important. Warmer (not approaching the boiling point, and in the absence of significant increases in the solubility of the particles) is generally better than colder.

- B. Materials such as tar, that may be solid at room temperature, may be liquid with a low enough viscosity for processing at elevated temperature.

Parameters such as the speed of the feed tank agitator, the type of feed pump impeller, and ambient cooling owing to seasonal temperature fluctuations, may adversely impact the separation. In biologically active systems, factors such as differences in pH, alkalinity or volatile solids may indicate a difference in the feed stock to the separation system.

Sigma limitation: efficiency The sedimentation that the sigma value attempts to quantify is only a portion of the task to be accomplished. By assumption, sigma allows comparison of centrifuges which are geometrically and hydrodynamically similar. In practice, an efficiency factor is often introduced to extend the use of sigma to compare dissimilar centrifuges. Therefore we can expand eqn [21]:

$$Q_2 = Q_1(\Sigma_2/\Sigma_1)(e_2/e_1) \quad [34]$$

again, if and only if $v_{s1} = v_{s2}$.

If the two centrifuges are geometrically and hydrodynamically equal, the efficiency factors cancel. Axelsson has attempted to quantify the efficiency of the various types of sedimenting centrifuges and has provided the data in Table 1.

Scale-up The sigma formula for the various types of imperforate centrifuges are listed in Table 2.

When testing a new material for separability on a centrifuge, a bottle centrifuge (Figure 6) is usually used to estimate the G-level required. To estimate size from the bottle centrifuge:

$$Q_B/\Sigma_B = (2g/\omega^2 t) \ln(2r_c/(r_c + r_1)) \quad [35]$$

By adapting eqn [34], the full-scale centrifuge (Σ_L) for the full-scale flow (Q_L) can be determined:

$$(Q_L/Q_B) = (\Sigma_L/\Sigma_B)(e_L/e_B) \quad [36]$$

$$\Sigma_L = \Sigma_B(Q_L/Q_B)(e_B/e_L) \quad [37]$$

where $e_B = 1$ and e_L is between 0.5 and 0.9.

Table 1 Efficiency of various types of sedimenting centrifuges

Sedimenting centrifuge type	Efficiency factor (e)
Disc stack	45–73%
Decanter	54–67%
Tubular bowl	90–98%

Table 2 Sigma formula for the various types of imperforate centrifuges

Centrifuge type	Sigma formula
Bottle centrifuge	$\omega^2 V/2g[r_c/(r_c + r_1)]$
Imperforate bowls (tubular, decanter, basket)	$2\Pi/(\omega^2/g)(\frac{3}{2}r_2^2 + \frac{1}{4}r_1^2)$
Disc stack	$(2\Pi n\omega^2/3g)(\cot \Theta(r_2^3 - r_1^3))$

The sizing should then be confirmed by testing the selected centrifuge type.

The sigma concept indexes the size of centrifuges based solely on sedimentation performance. Other criteria and limitations must also be considered. These limitations most often involve the ability of the centrifuge to handle solids once they are sedimented. This may require knowledge of solids residence time, G-level, solids transportability (conveyability or flowability), compressibility and recognition of the limits on torque and solids loading.

Filtering Centrifuges

Ideal System

Filtration systems, centrifugal or otherwise, usually conform to the same fundamental relationship, which is defined as:

$$Q/A = P/R \quad [38]$$

Figure 6 Bottle centrifuge (X represents the initial position).

where Q is the volumetric flow rate, and A is the cross-sectional area of the medium. P is the driving force, which is dependent on the equipment chosen. R is the resistance that depends on the materials being processed. Q/A , not surprisingly, is analogous to Q/Σ . The driving force (P) is proportional to the G-level. The bulk of the discussion revolves around how to determine the cake resistance (R).

Cake Drainage

The theory covering drainage in a packed bed is incomplete, especially when a centrifugal field is applied. It is an exceptional case when a theoretical solution might be applicable. Most of the work in this area involves numerical integration of experimental data if available, empirical rules, and simplifying assumptions. Liquid is held in the cake by various forces. Several flow mechanisms are proposed for liquid removal. In a centrifugal field, the acceleration is a function of radius from the centre of rotation which might cause changes in the packing of the bed and the acceleration of the liquid. The effective force on the particle is proportional to $(\rho_p - \rho_l)$, as the liquid in the bed drains $\rho_l \rightarrow 0$, so that the effective force on the particle changes. It is difficult to construct a useful theoretical model under these conditions that might be used in the absence of empirical data.

During cake deposition, a continuous head of liquid ranging in composition from that of the feed to an essentially clarified supernate may exist over the cake bed. If the cakes are slow draining a layer of clarified liquid may exist over the cake bed even after the feed is stopped. Draining under these conditions requires continuous flow through the cake. These interstitial spaces are assumed to be full. When a layer of free liquid no longer exists above the cake, the free liquid surface moves through the cake to an equilibrium position at the capillary height, leaving behind voids filled with gas or vapour. After bulk drainage of the larger voids, liquid still exists in the cake's upper portion in a film covering the surfaces of the solids and in partially filled voids having restricted outlets. Eventually, some of this liquid flows as a film to the continuous liquid layer at the capillary height. Typical drain time after the disappearance of a free liquid head above the cake is shown in Figure 7. Some essentially undrainable liquid exists within the body of each particle or in fine deep pores without free access to the surface except possibly by diffusion. This last type of liquid might be removed by evaporation or possibly by displacement with another liquid but cannot be removed mechanically by either

Figure 7 Typical drain time.

a gravitational or centrifugal field. Treatment of empirical data is discussed in the literature.

CHROMATOGRAPHY

Automation

E. Vérette, Gilson, Villiers-le-Bel, France

Copyright © 2000 Academic Press

The last 20 years have seen an important increase in published papers on chromatography, reporting fully automated systems or complete online techniques. This shows a strong interest in automation in chromatography to obtain faster, safer, more cost-effective and convenient analytical procedures, that satisfy regulatory compliance and good laboratory practice directives. Automation in chromatography takes place in the more general laboratory automation context, which is the application of computing, robotics, electronics and mechanical engineering technologies to laboratory problems for enhanced throughput, reproducibility and traceability. This has been made possible as a result of considerable improvements in equipment and techniques, from autosamplers, sample processors and reliable eluent delivery devices, to universal or more specific detectors, collectors, single point control software able to collect and handle accurate data (Figure 1) and, last but not least, laboratory information management systems.

The chromatographic techniques whose automation is principally discussed in this article are gas chromatography (GC), high performance liquid

chromatography (HPLC) and supercritical fluid chromatography (SFC). Other chromatographic methods such as planar chromatography can also be automated, but full automation is more difficult to achieve.

One of the most important aspects of automation is the introduction of interfaces between instruments and computers, and centralized user-friendly software for system control and data handling. The main qualities required for interfaces, designed to collect analog signals and digitize them to reflect detector output accurately, are good sampling rates and high resolution. Other important aspects of automation are directly related to the evolution of individual instruments, and the possibility of coupling them online. This article is not an exhaustive description of automation in chromatography, but highlights the principal trends in this field. It emphasizes sample preparation and application in chromatographic systems, multidimensionality and fully automated solutions widely used today such as high throughput screening and preparative chromatography.

Autosamplers

Not far behind computerized data acquisition and analysis, autosamplers are one of the biggest factors in automation, allowing long unattended series of analyses, therefore releasing the operator for other tasks. Autosamplers also give considerable improvement in reproducibility. Autoinjectors for HPLC, GC

Figure 1 A fully automated HPLC system including an autoinjector, a pump, a detector and a collector controlled by centralized software.

and SFC are generally of Cartesian displacement or of carousel types.

High Performance Liquid Chromatography

HPLC is considered to be the major chromatographic technique available today for involatile or heat-sensitive substances. Sample injection is commonly performed using a switching valve via an external or internal sampling loop. Sample containers range from simple vials with a wide range of volumes to different types of microtitre plates (96 and 384 wells), with the option of temperature control. Using 384-well microtitre plates, some modern instruments can store and handle over 4600 samples unattended. Many autosamplers have three injection modes, total, partial and centred loop filling, depending on the sample volume limitations. In recent years the need for faster analysis has been a major consideration; therefore, the shortest time required between two injections (injector cycle time) appears to be an important criterion for autoinjectors, and may be less than 20 s in the fastest. Other important criteria are injection precision and the level of carryover, with typical values below 0.3% (relative standard deviation) and 0.02% respectively for the best instruments.

Gas Chromatography

Because of its extremely high separation efficiency, speed of analysis and wide range of sensitive detectors, GC and particularly capillary GC is an appropriate procedure for analysing many compounds in a great variety of applications, provided these compounds are volatile, thermally stable and with reasonable polarities to avoid problems encountered with derivatization procedures. However, until recently its major critical point was the injection of large volumes, especially when traces of organic compounds have to be analysed, and the suitability of the sample solvent. The injector influences accuracy, precision, resolution and analyte recovery. The use of new automatic injection devices has provided the means to enhance the limit of detection significantly. Five modes of operation (split, split-less, direct, cold on-column injection, and programmed temperature vaporizer) allow maximum injector flexibility. Among these, the programmed temperature vaporizer (PTV) is of major utility for the automated injection of large sample volumes (Figure 2). This technique is based on the selective elimination of the solvent, while simultaneously trapping the components with a much lower volatility. Liquid samples are introduced into a large capacity, sorbent-packed liner inserted in the injector head. By temperature-programming

the liner, the solvent is vented through the split exit while analytes are retained. The split valve is then closed and the injector is rapidly heated to transfer the analytes to the GC column. With such a technique, injection volumes in split-less capillary GC can be increased up to 1 mL and this procedure therefore brings enormous improvements in limits of detection.

Static or dynamic headspace sampling, is another interesting way of injecting volatile compounds from complex matrices into a GC. In this process, the vapour in equilibrium above a sample held at constant temperature in a sealed vial is drawn and analysed. Headspace GC is used to analyse a wide range of compounds in solid and liquid complex matrices, and fully automated devices are available today with computer-activated heating and pneumatic systems.

Sample Preparation

For a long time, sample preparation has been considered to be the bottleneck of the analysis. However, the advances of automation in this area have until recently been distinctly more modest compared with other areas. The move towards automation in sample preparation occurred for several reasons, including higher productivity, fewer and more skilled laboratory personnel, better analytical results and less hazardous conditions. Basically, there are two almost complementary types of equipment, anthropomorphic arms and Cartesian liquid handlers, used according to the nature and quantity of samples to be processed and the preparation complexity (Figure 3). Anthropomorphic arms are capable of grabbing objects and moving them from one place to another with high accuracy. They need a set of dedicated stations to carry out different operations such as grinding, homogenizing, drying, weighing, etc. The principal preparation steps used with Cartesian (XYZ) samplers are dilution, addition of reagents or internal standards and mixing. With additional equipment they can also perform temperature control, evaporation or filtration.

Solid-phase Extraction (SPE)

SPE has become a technique of choice for sample clean-up and trace enrichment in the fields of pharmaceutical, clinical, food and environmental analysis. Indeed, it offers better versatility and selectivity than other sample preparation techniques. Compared with liquid-liquid extraction, it is quicker, it requires much less solvent, it prevents possible formation of emulsions, sample volumes can be smaller, and it is

Figure 2 Schematic representation of a PTV injector and temperature profile of injection.

much more amenable to automation. The US Environmental Protection Agency has adopted more than 20 SPE methods as alternatives to liquid-liquid extraction. SPE formats range from traditional disposable extraction columns and membrane discs to 96-well plates and SPE pipette tip configurations. Today, a wide range of sorbents is available to increase selectivity and/or simplify the SPE procedure, from silica to polymer-based phases, including speciality phases with mixed-mode functionality.

An experimental SPE procedure typically follows four steps – conditioning, loading, washing and eluting. With offline systems using disposable columns, liquids go through the extraction columns

either by aspiration (vacuum manifolds), or by positive air pressure; the latter can be completely automated. **Figure 4** shows typical SPE automation, based on the mobility of a dedicated rack consisting of three parts. After elution and a final mixing step, the eluate can be automatically introduced into the chromatograph via an injection valve for analysis.

Fully automated offline SPE brings an easy transfer of manual methods, which results in a quick transposition of hundreds of existing protocols with little additional development. Since the introduction of the large volume GC injection with a PTV injector interface, automated SPE has been extended to numerous GC applications. Some SPE instruments

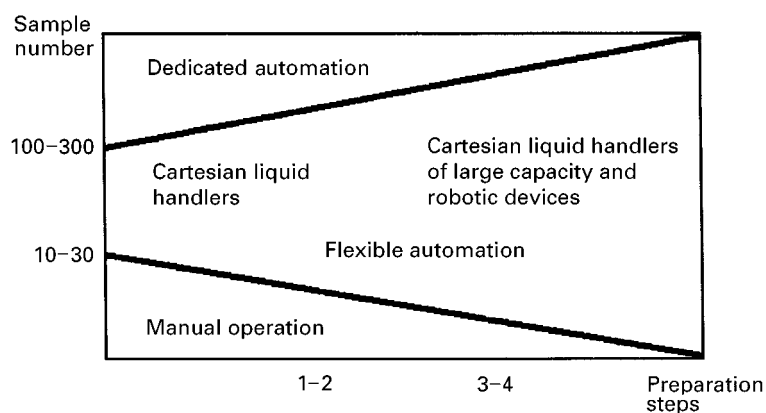

Figure 3 Diagram of estimated automation requirements according to sample number and preparation complexity.

propose a flexible process to develop new methods such as the possibility for multicollection, multi-modal SPE or column drying, and more recently the possibility of using 96-well SPE microplates with a multiple probe equipment.

In online configurations, an extraction cartridge is inserted as part of the chromatographic equipment, and is directly connected to the high pressure stream of the mobile phase. Such automated SPE equipment can use either the same cartridge for multiple extractions, or carry out automatic cartridge exchange. Online SPE processes are also known for pre-column concentration techniques, and may involve column switching or coupled-column procedures. The online approach provides high throughput and preserves the sample integrity, but the technique is still dependent on particular applications and the reproducibility of packing materials.

Solid-phase Microextraction (SPME)

SPME, introduced by Pawliszyn in the early 1990s, is a sample preparation and introduction method in which analytes migrate from a liquid, headspace or air sample on to a polymer (principally polydimethylsiloxane or polyacrylate) that is coated on a fused silica rod. The fibre is then displaced into a thermal or solvent desorption interface for analysis respectively by GC or HPLC. All these steps can be fully automated using autosamplers specifically adapted to SPME, such as the recent in-tube SPME device for HPLC. This technique, which is used repeatedly, provides fast, easy-to-use and inexpensive sampling, and eliminates organic solvents. Initially applied to the analysis of relatively volatile environmental pollutants in simple matrices, it now allows sampling of a broader range of analytes, including drugs in more complex media, with improved analytical performance.

Valve Switching Devices for Sample Preparation

Valve switching devices allow variable combinations of columns, mobile phases and/or detectors, which contribute to the overall system selectivity. When large numbers of substances are present in complex samples like biological fluids, and the compounds of interest are at very low concentrations, such devices are used sequentially to carry out sample clean-up and trace enrichment. Different set-ups are available depending on the type of application, permitting the transformation of offline multi-step methods to single-step procedures. The simplest configuration uses one pre-column between the sample injector and a six-port valve which rotates after venting the unwanted components to waste (straight-flush mode). A more powerful process can be achieved by operating in backflush mode, but necessitates additional equipment. In recent years, switching devices have regained interest due to the introduction of the bimodal restricted access sorbents. Designed for the deproteinization of biological samples, restricted access sorbents are characterized by a hydrophilic external surface incorporating reversed-phase coated pores. Interfering proteins are excluded from the pores by hydrophilic and size exclusion interactions, and low molecular analytes like drugs and metabolites are extracted and enriched on the bonded phase in the sorbent pores. This new type of separation medium is best used in the form of an extraction cartridge fitted to the six-port valve of a sampling injector, before analysis with a more conventional column.

A schematic diagram of a fully automated set-up including an auto-injector with two switching valves is shown on **Figure 5**, where a preliminary online filtration step is performed to extend the lifetime of the cartridge when analysing crude samples. After

Figure 4 Automated solid-phase extraction based on ASPEC™ (Gilson) technology. (A) The four basic steps: conditioning (C), loading (L), washing (W) and eluting (E). (B1) Conditioning, loading and washing over the drain container. (B2) Eluting into the collection tubes.

injection the filtration device is regenerated with suitable solvents in backflush mode. Membrane-based sample clean-up such as dialysis, electrodialysis and ultrafiltration is another efficient and innovative way of discarding macromolecular and microparticulate matters before analysis. These devices can be automated and associated online with a chromatographic system, mostly HPLC, using switching valves.

Figure 6 shows a commercially available system automatically performing liquid transfer steps like addition of internal standards or derivatization, dialysis and trace enrichment from crude samples, for the online routine analysis of a large number of samples. This instrument consists of a XYZ autosampler, equipped with a dual-syringe pump, a flat-bed dialyser inserting a porous membrane and two six-port valves. After each analysis, the system is completely regenerated.

Supercritical Fluid Extraction (SFE)

Supercritical fluids have physical and chemical properties that make them particularly useful for extraction of analytes from solid and liquid matrices. Above their critical temperature, they can be compressed to increase their density and therefore their solvating power; moreover, they keep gas-like viscosity and diffusivity, and they can easily be evaporated by lowering the pressure. Because of these properties, SFE has received much attention as an alternative to

Soxhlet extraction. Automated SFE can be incorporated online with various analytical techniques such as HPLC, GC or SFC.

Multidimensionality

In the analysis of complex samples, a single analytical column combined with a selective detector does not always provide the required sensitivity and selectivity. Automated multidimensional chromatography has emerged as a convenient answer to these

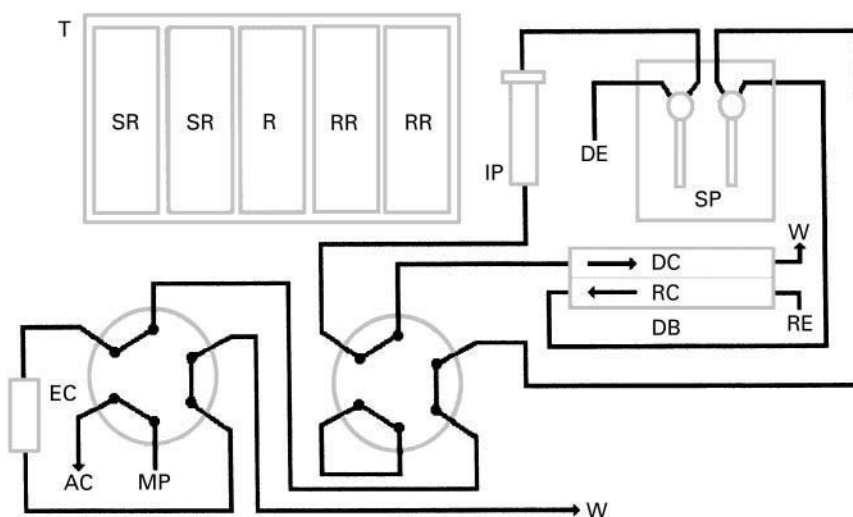

Figure 6 Online dialysis and trace enrichment of liquid samples using ASTED™ (Gilson) technology. problems. Multidimensional separation techniques constitute a powerful class of methods in which two or more independent steps are linked together. Roughly, multidimensionality includes two major branches: hyphenation and coupled-column techniques. A hyphenated instrument can be described as the combination of two (or more) instruments automated as a single integrated unit via a hardware interface whose function is to reconcile the output limitations of one instrument and the input limitations of the other.

Couplings of Chromatographs and Spectral Technique Devices

In recent years, numerous publications have described coupled techniques associating chromatographic instruments like HPLC, GC or SFC with sophisticated detectors or spectrometric devices, such as mass spectrometers (MS), MS coupled with diode array detector (DAD), MS-MS, Fourier transform infrared and nuclear magnetic resonance. However, for these online couplings, complete automation is generally required, and they are only feasible if suitable interfaces are available. Among these combinations, GC-MS and HPLC-MS are the most widely used in laboratories.

Gas Chromatography–Mass Spectrometry MS data provide the qualitative information for identification and characterization of sample components that is lacking in most other GC detectors. The availability of highly inert, durable and selective fused-silica columns and the ease of coupling GC systems with relatively low cost mass spectrometers make GC-MS a method of choice for numerous analyses, and this automated combination is now a routine analytical technique in many laboratories. The main restriction is that the analytes must be sufficiently volatile and thermostable for transfer to the vapour phase without decomposition, or that they can be derivatized to provide these properties.

High performance liquid chromatography–mass spectrometry Of all LC detectors, MS is a very powerful confirmatory tool for screening applications, and is widely used for impurity identification or quantification of drugs and metabolites in biological fluids. Nevertheless, no method of interfacing HPLC and MS exists that can be universally applied to all types of analyses. However, considerable progress has been made recently in the development of soft ionization techniques such as matrix-assisted laser desorption ionization, and also in sample introduc-

tion devices like particle beam, electrospray/ion spray or atmospheric pressure chemical ionization interfaces. When nonvolatile buffers like phosphates or ion-pairing agents are used, removal of these additives can be automatically performed, changing the phase system with additional equipment, using coupled-column and valve-switching techniques.

Couplings of Chromatographic Systems

These techniques are versatile and powerful, and are well suited to the separation of multicomponent mixtures. They include zone-cutting methods, in which fractions from one chromatographic column are usually transferred via a loop installed on a switching valve, to one (or more) secondary column(s) in series for additional separation(s), or to another chromatographic system. In LC-LC, a special area of interest of column-switching is the resolution of enantiomeric drugs in biological fluids, by coupling chiral systems to conventional reversed-phase columns. Other useful associations combine size exclusion or ion chromatography with reversed-phase chromatography. Parallel settings using switching valves are also possible for column and mobile-phase selection. Such systems have been reported for fully automated, rapid and easy method development to analyse different types of compounds, including enantiomers.

LC-GC is a very convenient combination which associates the selectivity of LC with the high efficiency capillary GC. Moreover, GC possesses many sensitive and specific detectors. Such a coupled technique enables the analysis of samples with complex matrices, and considerably prolongs the GC column lifetime. The first set-up was described by Majors in 1980; since then important improvements in development have been achieved. With this transfer technique, specific attention must be paid to interfaces. Several interfaces are available to couple the two systems online, such as on-column, loop-type and PTV interfaces which permit the transfer of large volume samples into the gas chromatograph. Insertion of a short trapping column between HPLC and GC also enables direct coupling from reversed-phase systems.

Fully Automated Dedicated Systems

The production of chemical compounds at the laboratory or plant scale requires fully automated and reliable separation techniques. This is true from discovery, through process control, to the final stage of purification and quality control of a new compound or drug. Numerous complete solutions exist today,

such as online systems available in biotechnology, which involve automated process monitoring for the determination of small organic molecules, and interactive controls of the physicochemical and biochemical growth conditions in culture media. In many fields, including combinatorial chemistry, preparative separations are certainly widely used and require the most complete online solutions.

Preparative Chromatography

The objective of preparative chromatography is to obtain sufficient quantities of compounds at the required purity, with the highest throughput and at the lowest price. Material to be purified can be simple or more complex, such as fermentation broths and natural products. In such instances, fully automated preparative HPLC on a laboratory scale (milligrams to grams) is one of the best separation techniques for this objective, and also because of its flexibility to accommodate frequent application changes and variable quantity ranges.

The requirements of a preparative HPLC system differ according to the quantity of product to be collected, and the nature and number of samples to be purified. However it should provide reliable and complete automation for unattended operations with error-handling methods, and total traceability of all events, including the collected fractions. Fraction collectors are key instruments in preparative HPLC, and should be selected according to their collection facilities and fractionation software. Devices exist that can perform peak collection with automatic

tracking of the baseline drift. With such instruments, collection is initiated if the detector signal is above user-set parameters in relation to threshold level and peak width. The graphic sample tracking which is feasible with some recent centralized software is also an important feature in preparative chromatography. Indeed, it can provide useful information to the user on sample identification, collection positions and associated chromatograms.

Since the introduction of independent programming of mobile-phase pressure, composition, and flow rate, SFC with packed columns has received considerable interest for several reasons, including its suitability and exceptional performances in preparative works. Consequently, this technique may become a serious competitor to preparative HPLC in the near future. **Figure 7** shows a completely automated system for analytical and preparative SFC. A versatile dual-valve autosampler of large capacity is used to perform both injection and collection. A solvent-less injection mode and a column-switching procedure are realized by two extra six-port valves. Such a system performs analytical development and switches easily and quickly to preparative chromatography for linear scale-up, and back to analytical for the purity check of the collected fractions. All these steps are automatically monitored by centralized software.

Analysis and Purification in Combinatorial Chemistry

Combinatorial chemistry appeared a few years ago in the pharmaceutical and biotechnological industries as

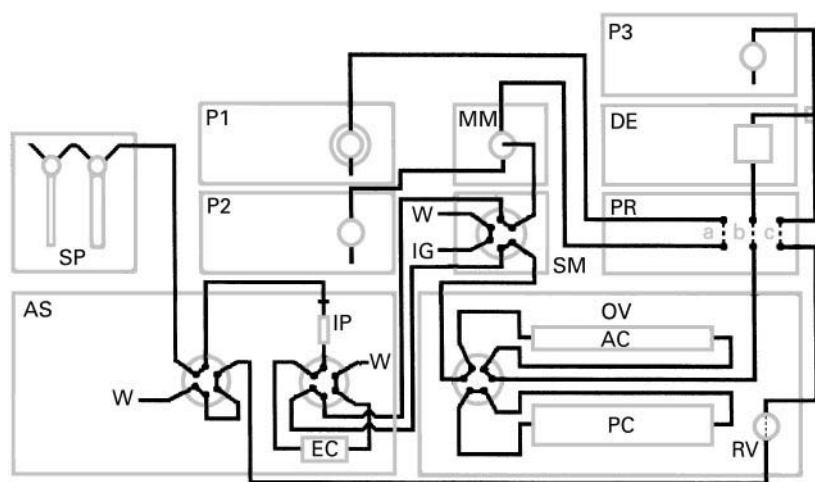

Figure 7 Automated analytical/preparative supercritical fluid chromatography on packed columns, with a solvent-less injection mode, based on Series SF3™ (Gilson) technology. AC, Analytical column; AS, dual-valve autosampler; DE, detector; EC, enrichment cartridge; IG, inert gas; IP, injection port; MM, mixing module; OV, oven; PC, preparative column; PR, pressure regulator (a, upstream pressure and pulse damper; b, heat exchanger; c, downstream pressure regulator); P1, liquid carbon dioxide pump; P2, modifier pump; P3, collection solvent pump; RV, pressure relief valve; SM, switching valve module; SP, dual-syringe pump; W, waste.

a novel approach to finding new drugs, and has undergone outstanding development since then. It is defined by a variety of automated high throughput synthesis techniques, to produce large numbers of small organic molecules, for screening these compounds against several biological targets for drug discovery. Combinatorial chemistry includes three basic steps – synthesis, candidate screening and library product purification – but chromatography is principally involved in the last two.

In drug candidate screening, library product verification can be performed with various analytical techniques. Among these, gradient reversed-phase HPLC with UV detection is widely used. Such a system, fitted with an autoinjector which accommodates microtitre plates, provides a robust and highly automated approach. Fast HPLC methods (generally of less than 5 min) generate up to 300 analyses per day per system and are required to produce libraries of products with widely differing polarity. These generic methods use short C_{18} columns with sharp slope gradients from acidified water to acidified organic solvents, high flow rates and UV detection set at 220 or 254 nm. Automated HPLC-MS, HPLC-DAD-MS and HPLC-MS-MS have also become important routine tools for the combinatorial chemist, because they provide structural information to identify the compounds which have been synthesized.

Automated purification to an extremely high level with sample quantities of up to 100 mg can be achieved with a preparative HPLC system equipped with an autoinjector and a fraction collector. The technique uses the same packing material and mobile phases as those used in analytical separation. Fast and easy clean-up can also be performed using SPE cartridges or microplates. Samples may therefore be processed in parallel with an automated device for optimum throughput. And last but not least, preparative SFC, although with limited applications so far, also provides a high productivity approach to purification, and in the near future should acquire a much bigger place in combinatorial chemistry.

Future Trends

Automation in chromatography has been a major preoccupation in recent years, mostly for pharmaceutical and clinical laboratories, and this will certainly be more intensive in the future, with concomitant developments in other fields like chemical, agrochemical, food or environmental analysis. The main goal is to provide more analyses giving the maximum and the most accurate information in the shortest time, at the lowest cost. This is the current situation in pharmaceutical and biomedical research

for high throughput screening in combinatorial chemistry, genomics or proteomics. Future trends in automation will surely follow the evolution of instruments, including mixed-mode techniques like capillary electrochromatography, more efficient interfaces, and more versatile and user-friendly software. They will also follow the progress in chromatographic media like restricted-access sorbents or advanced stationary phases with sub 3 μm particles for LC, and new materials for sample preparation such as 96-well SPE extraction plates.

Miniaturization in chromatography, including automated micro- and nano-techniques, is certainly an important step towards this goal, and a good example is given by the fast separation of complex mixtures with miniature gas chromatographs, which can now be performed in the field. Moreover, in addition to allowing the analysis of very limited volume samples with good sensitivity, and to reduce mobile-phase consumption, miniaturization tends to reduce work space, robot displacements and liquid transfers and consequently overall analysis time. The evidence of the release on the market of 384-well SPE extraction plates will obviously confirm this trend. Down-sizing even further, the use of 1536-well microtitre plates automated by sample processors equipped with distribution heads and chip format technology will certainly be expanded in the very near future. This goal involves refinement of the technique to carry out continuous separations with sub-second time resolution and attomole detection limits.

Convective Transport in Chromatographic Media

A. E. Rodrigues, LSRE Faculty of Engineering,
University of Porto, Porto, Portugal

Copyright © 2000 Academic Press

New liquid chromatographic media have been developed in the last decade containing large pores for convective mass transport and smaller diffusive pores to provide adsorption capacity. These permeable packings are at the heart of perfusion chromatography, patented in 1991, leading to better column efficiency and speed of separation with applications in the rapid analysis of biological macromolecules and preparative scale purification of proteins. This improved column efficiency is based on the concept of augmented diffusivity by convection, available from parallel development in the chemical reaction engineering area.

The analysis of column performance requires an extended van Deemter equation for the HETP (height equivalent to a theoretical plate) as a function of the superficial velocity. A methodology for obtaining basic data for design of perfusive chromatography is suggested involving elution chromatography of proteins in nonretained and frontal chromatography experiments.

Permeable Chromatographic Media

Packing materials in bead form can be grouped into four classes: homogeneous cross-linked polysaccharides (e.g. agarose), macroporous polymers based on synthetic polymers (e.g. POROS particles used in perfusive chromatography with large pores of 600–800 nm and diffusive pores of 50–100 nm), tentacular adsorbents allowing faster interaction between proteins to be separated and functional groups and materials based on the concept of ‘soft gel in a rigid shell’ combining the good capacity of soft gels with the rigidity of composite materials.

In conventional packings, solutes are carried to sites on the particle surface by bulk convective flow of the mobile phase through the column and then diffuse to binding surfaces inside the particle. The intra-particle diffusion process can be quite slow for large molecules (proteins, peptides). In order to maximize capacity and resolution, interaction with as many sites as possible is required; however, this will be more difficult at high flow rates and therefore trade-offs between speed, resolution and capacity are needed. In permeable, flow-through particles used in perfusive chromatography the flow rate can be increased one order of magnitude compared with conventional packings because of the short diffusion path length inside the microspheres.

New materials aim to achieve higher sorption capacity and better sorption kinetics. Some developments consider new geometries: fibres, membranes or discs (cellulose, polymethacrylate) or continuous beds (rods, monoliths). In continuous rods of acrylamide-acrylate polymers, flow pores are of 3–4 µm diameter and in methacrylate-styrene polymers large pores of 0.5–2 µm and even 20 µm are obtained with microspheres of less than 0.5 µm. Similar developments on continuous silica rods are taking place. In continuous bed technology, channels are of 3–5 µm with microspheres of 0.5–1 µm, whilst in bead form, packings are typically of 3–50 µm with pore size of 0.1 µm. Also superagarose beads of 300–500 µm have been prepared with superpores of 30 µm as well as 3 mm thick membranes. Table 1 reports examples of convective chromatographic media.

The Concept of Augmented Diffusivity by Convection

The design of chromatographic media aims to eliminate or reduce the mass transfer resistance inside particles by coating a nonporous support with active species, decreasing the particle size or increasing par-

ticle permeability as in convective chromatographic media (Figure 1). The use of flow-through particles (Figure 2) has been increasing recently in relation to protein separation by HPLC with perfusive chromatography. Intraparticle forced convection is a mass transport mechanism which, in addition to diffusive transport, cannot be neglected in large pore materials. The key concept to be retained is the augmented diffusivity by convection, which explains why the efficiency of adsorptive processes is improved with convective chromatographic media.

The effect of intraparticle convective flow due to a total pressure gradient was quantified in 1982 by a group measuring effective diffusivities by chromatographic techniques. The analysis of experimental results was first made with a conventional model which included an apparent diffusion (lumping diffusion and convection) of tracer inside pores. The apparent diffusivity was found to increase with the superficial velocity. From the equivalence of the conventional model and a detailed model which allows for the separate contribution of diffusive and convective flow (Figure 3) the apparent diffusivity or augmented diffusivity by convection, \tilde{D}_e was calculated for an inert tracer as a function of the true effective diffusivity

D_e and the intraparticle mass Peclet number λ :

$$\tilde{D}_e = D_e \frac{1}{f(\lambda)} \quad [1]$$

where:

$$f(\lambda) = \frac{3}{\lambda} \left(\frac{1}{\tanh \lambda} - \frac{1}{\lambda} \right)$$

The intraparticle Peclet number, λ , is the ratio between the time constant for pore diffusion, τ_d , and the time constant for intraparticle convection, τ_c . For slab geometry, $\tau_d = \varepsilon_p \ell^2 / D_e$ and $\tau_c = \varepsilon_p \ell / v_0$ so $\lambda = v_0 \ell / D_e$ where ℓ is the half-thickness of the slab particle and v_0 is the intraparticle convective velocity inside large pores; for sphere geometry with particle radius R_p , the diffusion time constant is $\tau_d = \varepsilon_p R_p^2 / D_e = R_p^2 / D_p$ and $\lambda = v_0 R_p / 3 D_e$.

The enhancement of diffusivity by intraparticle convection is $1/f(\lambda) = \tilde{D}_e / D_e$ and so the apparent diffusion time constant $\tilde{\tau}_d = \tau_d f(\lambda)$. Figure 4 shows the enhancement factor \tilde{D}_e / D_e as a function of the intraparticle Peclet number λ . At low bed superficial velocities, u_0 , the convective velocity inside pores, v_0 , is also small; therefore $f(\lambda) = 1$ and $\tilde{D}_e = D_e$ (diffusion-controlled case); at high superficial velocities u_0 , and therefore high v_0 and high λ ,

Figure 1 Strategies for eliminating or reducing intraparticle mass transfer resistances. (Reprinted from Rodrigues AE (1997) with permission from Elsevier Science.)

Figure 2 An example of permeable or flow-through chromatographic media with large pores and gel microspheres.

$f(\lambda) = 3/\lambda$; the augmented diffusivity is $\tilde{D}_e = v_0 \ell / 3$ for slab geometry and $\tilde{D}_e = v_0 R_p / 9$ for spheres (convection-controlled case), which depends only on the particle permeability, fluid viscosity and pressure drop across the particle.

Column Performance Using Convective Chromatographic Media

Conventional Packings

The column performance can be assessed in terms of HETP as a function of bed superficial velocity

Figure 3 Analogues of mass transport mechanisms in chromatographic media – model equivalence.

Figure 4 Enhancement factor \tilde{D}_e/D_e versus intraparticle Peclet number λ . (Reprinted from Rodrigues AE (1997) with permission from Elsevier Science.)

following the classic van Deemter analysis. The van Deemter equation for linearly retained species in conventional packings of sphere geometry is:

$$\text{HETP} = A + \frac{B}{u_0} + \frac{2}{15} \frac{\varepsilon_p(1 - \varepsilon_b)b^2}{[\varepsilon_b + \varepsilon_p(1 - \varepsilon_b)b]^2} \tau_d u_0 \quad [2]$$

where ε_p is the intraparticle porosity, ε_b is the bed porosity and $b = 1 + \{(1 - \varepsilon_p)/\varepsilon_p\}K$ is the adsorption equilibrium parameter for a linear isotherm with slope K . In a condensed form the van Deemter equation is:

$$\text{HETP} = A + \frac{B}{u_0} + C u_0$$

with:

$$C = \frac{2}{15} \frac{\varepsilon_p(1 - \varepsilon_b)b^2}{[\varepsilon_b + \varepsilon_p(1 - \varepsilon_b)b]^2} \tau_d$$

For protein separation the B term is negligible and the plot HETP versus u_0 in HPLC is a straight line in most of the domain when conventional supports are used. Moreover, the HETP increases with the square of the particle size.

Permeable Packings

For convective chromatographic media, since $\tilde{\tau}_d = \tau_d f(\lambda)$, the extended van Deemter equation (Rodrigues equation) is:

$$\text{HETP} = A + \frac{B}{u_0} + Cf(\lambda)u_0 \quad [3]$$

In the above equation one can notice that the last term pertaining to intraparticle mass transfer is reduced for permeable particles since $f(\lambda) < 1$. The van Deemter equation for conventional packings and Rodrigues equation for large pore supports are shown in Figure 5. At low velocities both equations lead to similar results. However, at high superficial velocities the last term in the Rodrigues equation becomes a constant since the intraparticle convective velocity v_0 is proportional to the superficial velocity u_0 . The HETP reaches a plateau which does not depend on the value of solute diffusivity but only on particle permeability and pressure gradient (convection-controlled limit). The column performance with permeable adsorbents is improved since HETP is reduced when compared with conventional packings and the speed of separation can be increased without losing column efficiency.

Bidisperse Chromatographic Media

In perfusive chromatography, packings contain both convective large pores and smaller diffusive

Figure 5 HETP versus superficial velocity u_0 (van Deemter equation for conventional packings and Rodrigues equation for large pore packings). (Reprinted from Rodrigues AE (1997) with permission from Elsevier Science.)

Figure 6 Influence of the ratio of time constants for diffusion in macropores and gel microspheres δ on the HETP versus u_0 plot for bidisperse permeable packings. (Reprinted from Carta G and Rodrigues AE (1993) with permission from Elsevier Science.)

pores. Carta and Rodrigues provided an equation for the column performance measured by HETP:

$$\text{HETP} = A + \frac{B}{u_0} + C \left\{ f(\lambda) + \frac{b-1}{b^2 \delta} \right\} u_0 \quad [4]$$

where $\delta = (D_c/r_c^2)/(D_p/R_p^2)$ is the ratio of time constants for diffusion in macropores and in microspheres with radius r_c . Figure 6 shows the effect of δ on the HETP versus u_0 plot when the fraction of flow permeating the packing is 1%. A criterion to determine when microparticle diffusion is the limiting step is given by:

$$\frac{b-1}{b^2 \delta} \gg f(\lambda)$$

Extension to Include Adsorption/Desorption Kinetics

In protein separation by high performance liquid chromatography (HPLC) with flow-through particles, the effect of convective flow inside pores (say, 1% of the total flow through the bed) is sufficiently important to enhance the low diffusion coefficient for proteins ($\approx 5 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$) and intraparticle Peclet numbers λ of 30 are easily obtained. When the kinetics of adsorption/desorption is considered with rate $r_{\text{ads}} = k_a c_i' - k_d q_i'$ where c_i' and q_i' are the species concentrations in the fluid phase inside pores and in the adsorbed phase, respectively and k_a and k_d are the kinetic constants for adsorption and desorption, the extended van Deemter equation becomes:

$$\text{HETP} = A + \frac{B}{u_0} + C \left\{ f(\lambda) + \frac{5}{Bi_m} + \frac{3(b-1)}{b^2 \phi_d^2} \right\} u_0 \quad [5]$$

Figure 7 Effect of adsorption/desorption kinetics on HETP versus superficial velocity u_0 . (Reprinted from Rodrigues AE *et al.* (1992) Influence of adsorption/desorption kinetics on the performance of chromatographic processes using large-pore supports. *Chemical Engineering Science* 47: 4405–4413, with permission from Elsevier Science.)

Parameters are the Biot number $Bi_m = k_f R_p / D_e$, accounting for film mass transfer and the Thiele modulus $\phi_d = \sqrt{k_d \tau_d}$. Figure 7 shows the effect of ϕ_d on the HETP versus u_0 plot. The performance of permeable packings is still better than that of conventional materials; intraparticle convection enhances pore diffusivity but has no effect on the mechanism of adsorption/desorption. Adsorption/desorption kinetics have to be taken into account in process such as affinity chromatography.

Methodology for Design

Estimating Intraparticle Peclet Number λ

The importance of convective flow in permeable particles can be assessed by intraparticle Peclet number λ . The convective velocity v_0 inside pores can be calculated from the equality of pressure drops across the particle Δ_p/d_p and across the bed $\Delta P/L$; in laminar flow both for the bulk fluid phase and pore fluid as in HPLC we obtain:

$$v_0 = \frac{B_p}{B_b} u_0$$

where B_b and B_p are bed and particle permeability, respectively. The fraction of flow rate entering the column which goes through the macropores by convection is:

$$(1 - \varepsilon_b) \left(\frac{B_p}{B_b} \right)$$

Bed Permeability

The measurement of the bed pressure drop, ΔP , versus u_0 allows the calculation of bed permeability. In laminar flow, the pressure drop ΔP across a bed of length L packed with particles d_p is given by Darcy's law:

$$\frac{\Delta P}{L} = \frac{\eta u_0}{B_b}$$

where:

$$B_b = \frac{\varepsilon_b^3 d_p^2}{150(1 - \varepsilon_b)^2}$$

Bed permeabilities B_b are obtained from the slope of the plot $\Delta P/L$ versus u_0 and then the bed porosity ε_b can be calculated. As a typical example for a POROS Q/M (PE Biosystems, USA) column 4.6 mm i.d. \times 100 mm long with a bed volume of 1.7 mL filled with 20 μ m particles, the bed permeability is $B_b = 2.35 \times 10^{-9} \text{ cm}^2 \text{ s}^{-1}$ and $\varepsilon_b = 0.34$.

Elution Chromatography with Nonretained Proteins

Elution chromatography experiments under non-retained conditions ($b = 1$) allow the understanding of mass transport inside particles. Flow rates up to 10 mL min⁻¹ corresponding to superficial velocities of 1 cm s⁻¹ were used. The diffusivities of proteins myoglobin, ovalbumin and bovine serum albumin (BSA) in aqueous solution at 25°C are 16.1×10^{-7} , 6.4×10^{-7} and $1 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$, respectively.

The HETP is calculated from the experimental chromatographic peaks by:

$$\text{HETP} = \frac{\sigma^2 L}{\mu_1^2}$$

where σ^2 is the peak variance, μ_1 is the first moment of the peak, μ_2 is the second moment and L is the column length. Figure 8 shows the experimentally measured reduced HETP $h = \text{HETP}/d_p$ as a function of the bed superficial velocity.

The efficiency of chromatographic columns can be characterized by the HETP; for columns packed with permeable packings, eqn [3] applies. The A term accounts for eddy dispersion effects and becomes a constant at high superficial velocities, $A = 2d_p$; $B = 2D_m$ and so the term B/u_0 can be neglected in the case of proteins. The simplified equation for HETP with permeable packings is $\text{HETP} \cong A + C f(\lambda) u_0$. In the low velocity region

Figure 8 HETP versus superficial velocity u_0 for elution chromatography of proteins under unretained conditions in a POROS Q/M column. Solvents were TRIS-HCl 50 mmol L⁻¹, pH 8.6, mixed with NaCl 0.5 mol L⁻¹ at 22°C. Circles, myoglobin; squares, ovalbumin; triangles, bovine serum albumin; continuous line, Rodrigues' equation. (Reprinted from Rodrigues AE *et al.* (1996) Protein separation by liquid chromatography using POROS Q/M particles. *Chemical Engineering Journal* 61: 191–201, with permission from Elsevier Science.)

where pore diffusion is the controlling mechanism of mass transfer, the slope of HETP versus u_0 is

$$C = \frac{1}{30} \frac{v}{(1+v)^2} \frac{\varepsilon_p}{\varepsilon_b} \frac{d_p^2}{D_e}$$

At high flow rates a plateau is reached with:

$$H_{\text{plateau}} = A + \frac{3}{5} \frac{v}{(1+v)^2} \frac{\varepsilon_p}{\varepsilon_b} \frac{B_b}{B_p} d_p$$

where:

$$v = \frac{(1 - \varepsilon_b)}{\varepsilon_b} \varepsilon_p$$

When the particle structure characterized by the intraparticle porosity, ε_p , is known, the initial slope and the plateau values provide measured values of D_e and B_p .

The straight line at low flow rates crosses the plateau at critical point where

$$u_{0,c} = \frac{18D_e}{d_p} \frac{B_b}{B_p}$$

For POROS Q/M, $\varepsilon_p = 0.5$ and $B_p = 1.5 \times 10^{-11}$ cm² for an experimental h plateau of 36 (reduced HETP) and $D_e = 7 \times 10^{-8}$ cm² s⁻¹.

Figure 9 Adsorption equilibrium isotherm for bovine serum albumin on POROS Q/M packing. (Reprinted from Rodrigues AE *et al.* (1996) Protein separation by liquid chromatography using POROS Q/M particles. *Chemical Engineering Journal* 61: 191–201, with permission from Elsevier Science.)

Frontal Chromatography Experiments

In frontal chromatography experiments a solution of protein with concentration c_0 is continuously passed through the column under retained conditions. The breakthrough curve is measured from which the amount of protein retained in the adsorbent, q_0^* is calculated by mass balance leading to a point on the adsorption equilibrium isotherm. The adsorption equilibrium isotherm of BSA in POROS Q/M is shown in Figure 9 and follows the Langmuir equation. Breakthrough curves with BSA at feed concentration of 2 mg mL⁻¹ and various flow rates merge together when the outlet concentration is normalized by the feed concentration and the time is reduced by the stoichiometric time, as shown in Figure 10. Moreover, breakthrough curves are very sharp, indicating that the useful dynamic capacity approaches the total column capacity.

Future Developments

Convective chromatographic media have found applications in the preparative chromatography of peptides and proteins. The use of these materials in preparative and industrial scale simulated moving bed (SMB) technology for chromatographic processes will eventually occur in view of the trade-off between pressure drop and packing efficiency; the simplified design of the SMB unit with simple linear driving force models to describe intraparticle mass transfer is straightforward, using an apparent mass transfer coefficient $\tilde{k} = k/f(\lambda)$.

Figure 10 Normalized breakthrough curves for BSA 2 mg mL^{-1} , c/c_0 versus t/t_{st} , on POROS Q/M column at various flowrates. Continuous line, 2 mL min^{-1} ; dashed line, 5 mL min^{-1} ; dotted line, 7 mL min^{-1} . (Reprinted from Rodrigues AE *et al.* (1996) Protein separation by liquid chromatography using POROS Q/M particles. *Chemical Engineering Journal* 61: 191–201, with permission from Elsevier Science.)

Continuous bed technology is a promising area which allows convective flow in wider channels and at the same time smaller diffusion limitations in microspheres since they have a very small diameter.

Correlation Chromatography

H. C. Smit, University of Amsterdam, Amsterdam, The Netherlands

This article is reproduced from Encyclopedia of Analytical Science, Copyright © 1995 Academic Press

Principles

Correlation chromatography (CC, multiplex chromatography, multiple input chromatography)

belongs to the family of multiplex methods and is essentially statistical in nature. It is a typical example of an integrated product of chemometric principles and an analytical technique. A schematic set-up of a CC system is shown in Figure 1.

In conventional chromatography the sample is injected over a short time, and the response of the chromatographic system – the chromatogram – can be considered as an impulse response. In CC the input

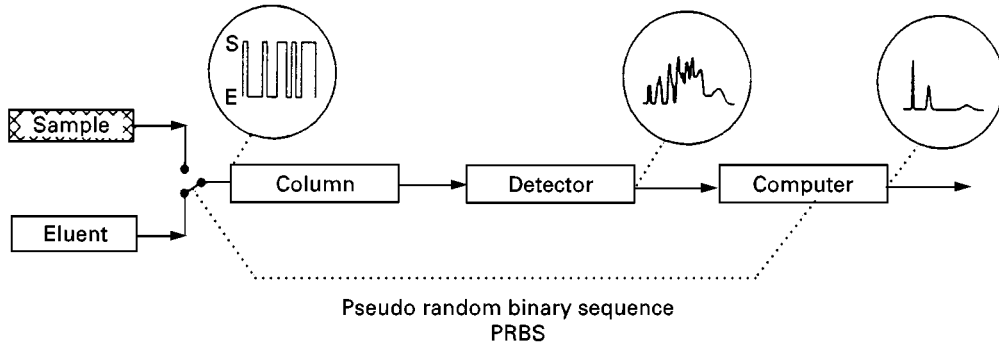

Figure 1 Mechanical valve-controlled correlation chromatography system: s and e correspond to sample and eluent injection, respectively.

flow of the column is rapidly switched between the sample and the eluent, according to a (pseudo) random pattern. A cross-correlation function (correlogram) of the random input signal and the resulting very complex detector signal is also identical to the impulse response (chromatogram) of the chromatographic system, if the input satisfies certain conditions. In other words, the correlogram is identical to a conventional chromatogram obtained by a pulse-shaped injection.

In CC the sample is usually injected according to a pseudo random binary sequence (PRBS) pattern $p(i)$, where i is the discrete time. A PRBS is a binary noise with a specific length M , the sequence length, of $2^n - 1$ periods (n is a positive integer) controlled by a clock; the only levels are $+1$ and -1 , or 1 and 0 . The M clock periods correspond to $I = 2^n - 1$ injections. The periodic nature of the PRBS input signals yields low estimate variance of the estimation of statistical quantities such as correlation functions if taken over an integer number of sequences.

The signal power of a PRBS, determining the final intensity of the detector response, is much higher than that of an impulse-like injection function with similar amplitude, and it is equally spread over the frequency range of the chromatographic system. This 'white noise' property is essential for the application of CC. In addition the levels can be used to control simple on/off valves, corresponding to injection of sample or mobile phase.

The detector signal y_i is built up of noise-free chromatograms $h(i)$ shifted in time, according to the PRBS pattern, plus detector noise $n(i)$:

$$y(i) = \sum_{j=0}^{M-1} [h(j), p(i-j)] + n(i) \quad [1]$$

The PRBS length is chosen to be equal to or longer than the time duration of the comparable chromatogram obtained from a single injection. The detector

signal becomes circular after one PRBS sequence, the so-called presequence. The calculation of a correlogram comparable with a similar chromatogram requires the inverse of the PRBS, defined as the function $p^{-1}(i)$, producing a Kronecker delta function $\Delta(i)$ after circularly cross-correlating with $p(i)$:

$$R_{p^{-1}p}(i) = \frac{1}{M} p^{-1}(j+i) \cdot p(j) = \Delta(i)$$

$$\Delta(i) = 1 \quad \text{for } i = 0$$

$$\Delta(i) = 0 \quad \text{for } i \neq 0. \quad [2]$$

Owing to the special properties of a PRBS, the inverse calculated from a PRBS with one point per period and levels 1 and 0 gives the same PRBS, but with levels $+M/I$ and $-M/I$ instead of $+1$ and 0 . Cross-correlating the detector signal $y(i)$ with the inverse $p^{-1}(i)$ results in a correlogram with a reduced noise level. In the calculations, non-correlated (white) noise is assumed:

$$\begin{aligned} R_{p^{-1}, y}(k) &= \frac{1}{M} \sum_{i=0}^{M-1} [p^{-1}(i+k) \cdot y(i)] \\ &= \frac{1}{M} \sum_{i=0}^{M-1} \left\{ p^{-1}(i+k) \cdot \left(\sum_{j=0}^{M-1} [h(j) \cdot p(i-j)] + n(i) \right) \right\} \\ &= \sum_{j=0}^{M-1} \left\{ h(j) \frac{1}{M} \sum_{i=0}^{M-1} [p^{-1}(i+k) \cdot p(i-j)] \right\} \\ &\quad + \frac{1}{M} \sum_{i=0}^{M-1} p^{-1}(i+k) \cdot n(i) \end{aligned} \quad [3]$$

Considering the levels $+M/I$ and $-M/I$ for $p^{-1}(i+k)$, $p^{-1}(i+k) \cdot n(i)$ can be replaced by

$(M/I) \cdot n(i, k):$

$$R_{p^{-1}, y}(k) = \sum_{j=0}^{M-1} [h(j)\Delta(k-j)] + \frac{1}{M} \sum_{i=0}^{M-1} \frac{M}{I} \cdot n(i, k) \quad [4]$$

Adding M noncorrelated points for every k results in noise with a standard deviation (SD) of $M^{1/2}$ times the original SD of the noise:

$$R_{p^{-1}, y}(k) = h(k) + \frac{M^{1/2}}{I} n(k) \approx h(k) + \sqrt{\frac{2}{I}} n(k) \quad [5]$$

With one point per period, the detector signal can also be cross-correlated with the original PRBS. This produces a comparable correlogram multiplied by a factor I/M .

A similar derivation can be made in the continuous time domain. It has been shown that the resulting cross-correlogram is identical to a chromatogram obtained from an injection with a profile equal to the autocorrelogram of the input sequence. For this reason this autocorrelogram is sometimes referred to as the 'virtual injection' profile. Sometimes a 'true' random binary sequence is used. In that case other deconvolution methods are necessary, such as deconvolution in the Fourier domain.

The correlation procedure can be continued for an arbitrary integer number of sequences. Theoretically, noise not correlated with the input pattern can be reduced to any desired level – but at the cost of time – assuming that the chromatographic system is stationary and that enough sample is available. The noise reduction in only one sequence is about a factor of 10 to 20.

Correlation techniques can be applied in different column separation methods, applications in gas chromatography (GC), liquid chromatography (LC) and capillary zone electrophoresis (CZE) are known. Particularly in LC and CZE, the detection limit can be a problem and correlation techniques in principle offer possibilities to increase the signal-to-noise ratio considerably without preconcentration of the sample. Another feature is the possibility of using CC for continuous monitoring; CC allows a fast and almost continuous updating of the value of the varying concentrations to be monitored. However, the moving average effect, typical for the correlation procedure, limits the highest frequency that can be monitored. CC permits to monitor a frequency about a factor of 2 higher than conventional chromatography. A considerable improvement is possible, if the multiple injection (PRBS) input is maintained, but the correlation procedure is replaced by non-linear fitting. The time-varying concentra-

tions are described as functions of the time and a number of parameters are optimized in the fitting procedure. A detector signal is calculated using the parameters, the known PRBS and known peak shapes; the squared differences with the real detector signal are minimized. The maximum frequency is not determined by the chromatogram length but by the peak width, orders of magnitude better.

Instrumental Requirements

The separation system, column, detector and separation conditions are similar in CC and in conventional chromatography. Nonlinearity of both the column and the detector, and poor stability, i.e. changing chromatographic conditions during the procedure, influence the correlation procedure, resulting in a disturbed baseline. Modern chromatographic systems fulfil the stringent demands of CC in this respect. An important modification is the special injection device required. Such a device has to meet several demanding requirements such as high reproducibility, absence of memory effects, high switching speeds, rugged design (no wear and tear problems) and controllability by a computer. Incorrect injection will cause disturbances (ghost peaks) are specific relative positions on the time axis, and in general cause so-called 'correlation noise' proportional to the amplitude of the real peaks. This therefore limits the determination of traces in the presence of the main components. Injection of sample for one clock period of the PRBS ideally results in an amount of sample transported to the column that is solely dependent on the value of the PRBS in the clock period concerned; 1 represents injection of sample and 0 represents no injection of sample. However, in general the injection is not ideal. After each 0 to 1 transition less than 100% of the ideal amount of sample is injected; and after each 1 to 0 transition a percentage of the sample is still fed into the column. This phenomenon gives rise to PRBSs shifted in time, resulting in the ghost peaks mentioned. Disturbances due to nonsymmetric and reproducible nonideal injection can be corrected. A reliable, accurate and simple injection system, meeting all demands of correlation LC, is obtainable. It is based on a common 8-port or 10-port LC valve, two equal sample loops and a valve actuator.

Computer Requirements

The appropriate hardware and software for injection control and data processing are essential in CC. Off-line data processing is possible, but a flexible and user-friendly program running on a microcomputer is to be preferred. The computer requirements

are modest: a standard PC with 640-kbyte memory is sufficient. A hardware card for controlling the valves, and an A/D converter (12 bits, minimum sampling frequency 10 Hz), including an anti-aliasing filter to prevent back-folding of high-frequency noise, are necessary. The software includes the generation of an arbitrary number of PRBSs, with selectable duration of the clock period and $2^n - 1$ clock periods in a sequence; n is integer number mostly between 5 and 12. The standard deviation of the smallest (first) peak and the desired resolution determine the clock period.

The data processing is relatively simple. Straight-forward cross-correlation may be replaced by the application of an off-line Hadamard transform procedure, speeding up the calculation. Display of the selected parameters (clock period, sequence length, number of sequences), the time varying detector signal, the on-line calculated correlogram, and possibly the injection PRBS are indispensable for application in practice.

Advantages and Disadvantages Compared with Conventional Chromatography.

The main advantage of CC is the improvement of the signal-to-noise ratio without preconcentration in a relatively short time. The resulting lower detection limit makes the technique very suitable for trace analysis. Another important advantage is that the compounds to be analysed remain on the average in their original chemical environment. This property of CC is particularly useful if compounds present in the sample degrade easily once isolated from their matrix. Another feature is the possibility of continuous monitoring of the varying concentrations encountered in process analysis. An interesting possibility is the strong reduction of effects due to nonlinear behaviour of the chromatographic system. When using CC, non-linear affected separations may improve drastically, although correlation noise may arise. Chromatographers need no special knowledge or skill to use CC in daily practice.

Possible disadvantages are the high demands on the chromatographic system, particularly the injection (reproducibility, wear and tear); the possible correlation noise, mainly due to injection errors; the extra sample required; and the extra time. In addition, the separation conditions are not exactly the same as in conventional chromatography, because of the continuous presence of sample throughout the column. The improvement of the signal-to-noise ratio is less than when the analytical signal itself is increased by a comparable preconcentration of the sample. How-

ever, preconcentration is often cumbersome or even undesirable, for example because of poor reproducibility.

The principles of CC are based on the assumption of stability of the system. Therefore, the application of gradient elution or programmed temperature techniques is out of the question in normal CC.

Modifications

Differential CC

The distortions of the correlogram caused by imperfect injection and nonlinearities are proportional to the concentration differences between the compounds in the sample and the eluent. CC can be used in a differential mode. The differences mentioned can be made much smaller by making the eluent almost equivalent to the sample by adding the (known) main components, present in the sample, to the eluent. Also, another sample – possibly modified for optimum separation conditions – can be used as eluent; only differences between the samples are measured, resulting in positive and negative peaks in the correlogram. This can be very useful in environmental analysis and trace analysis of samples with a relatively complex matrix.

Simultaneous CC (SCC)

In principle, it is possible to determine simultaneously n different samples on the same column, each injected according to its own mutual uncorrelated random pattern, using multiplex techniques. Completely uncorrelated (pseudo) random patterns in one sequence are impossible. However, the use of only one long PRBS for each sample, with a time shift equal to an integral number of chromatogram duration different for each sample, allows simultaneous CC. The correlation time is equal to $n + 1$ chromatogram lengths. This technique can be used for high precision chromatography. Unknown sample and calibration standards can be processed under exactly the same conditions, resulting in a very accurate calibration. The determination of pure compounds simultaneously with a complex sample gives the exact place and peak shape of these compounds in the correlogram. This can be used for optimization purposes, for optimum intensity estimation, and for resolving strongly overlapped peaks.

Single-Sequence CC (SSCC)

Single-sequence correlation chromatography is an intermediate between single-injection chromatography and CC. The injection volume is significantly enlarged in comparison to single-injection chromatog-

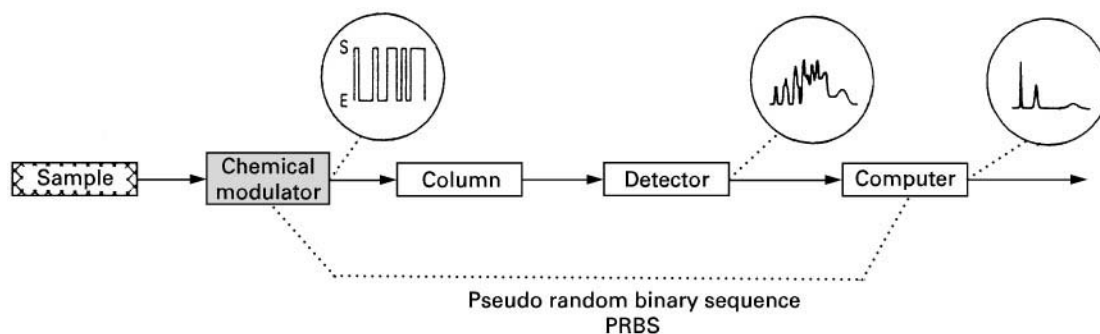

Figure 2 Chemical modulation correlation chromatography system.

raphy. However, the rectangular input function is modulated with a fine structure; one sequence of a PRBS. A deconvolution procedure allows the preservation of good peak resolution for fast-elution narrow peaks, while the other more broadened peaks are processed in a conventional way. In both cases the signal-to-noise ratio is improved. Gradient elution liquid chromatography (or programmed temperature GC) is still applicable, in contrast to conventional correlation and multiplex techniques.

Special attention has to be given to deconvolution errors due to the transient nature of the signals. Some noise frequencies may be amplified enormously if the number of points used for deconvolution is not optimally chosen.

Chemical Concentration Modulation CC

Chemical concentration modulators can be used in CC instead of mechanical injection valves. They can be considered as a chemical switch positioned at the head of the column. The eluent, which is continuously pumped through the system, contains the sample. In 'off' position of the switch nothing happens

and a constant sample concentration is introduced into the column. In the 'on' position a chemical reaction takes place in the cell, causing certain components to react, yielding reaction products with different chemical structures and different retention and detection characteristics. The chemical reaction may add selectivity to the method. Nonreacting components will not influence the correlogram, because of the different properties of CC. **Figure 2** shows a set-up of a chemical modulation CC system.

Several modulators in gas CC, both destructive and nondestructive, are known. Examples, particularly suited for trace analysis in air, are the hot-wire modulator, the spark modulator, and the thermal desorption modulator. In correlation LC, electrochemical concentration modulation has been tried successfully.

Illustrative Examples

The performance of correlation LC, compared with conventional LC, can be illustrated with a calibration graph as shown in **Figure 3(A)**. Phenol was measured

Figure 3 (A) Calibration graph with fluorimetric detection for five concentrations of phenol ($0.01 \mu\text{g L}^{-1}$ to $100 \mu\text{g L}^{-1}$); s and c indicate single injection and correlation, respectively. For each point the chromatogram length or the correlation time (min) is given. The bars indicate $\pm 3\sigma$ (standard deviation of the peak area). (B) Correlogram of a $0.01 \mu\text{g L}^{-1}$ phenol sample. The detection limit is about $0.001 \mu\text{g L}^{-1}$; 80 min correlation time.

Figure 4 LC analysis of PAH samples by single-injection (SI) and correlation (CC 511 – the number of clock periods in the Pseudo Random Binary Sequence) chromatography under similar separation conditions.

at a five concentrations: 0.01 to 100 $\mu\text{g L}^{-1}$. The three higher concentrations (1–100 $\mu\text{g L}^{-1}$) were determined by conventional reversed-phase chromatography, the three lower concentrations (0.01–1 $\mu\text{g L}^{-1}$) by CLC. Measurements at the 1 $\mu\text{g L}^{-1}$ level were done by both techniques. The bars indicate the peak area $\pm 3\sigma_1$ (arbitrary units), where σ_1 is the standard deviation of the integrated noise. The correlation time is 1, 3 and 16 sequences or chromatogram lengths, corresponding to 5, 15 and 80 minutes, respectively.

Figure 3(B) shows the correlogram of a very low concentration of phenol for 80 minutes of correlation. The detection limit in this case is approximately 0.003 $\mu\text{g L}^{-1}$. For a comparison with conventional LC it must be noted that the injection volume injected in one clock period of the PRBS is 48 μL , a factor of 2.4 more than the 20 μL single injection.

Another example of the possibilities of CLC is shown in Figure 4. Here a diluted rather complex standard material was analysed, containing a number of compounds at different known concentrations. The separation is not optimal, but the condi-

Table 2 Concentrations of the compounds in the samples used in the SCC experiment

	Concentration (mg L^{-1})		
	Naphthalene	Anthracene	1,2-Benzanthracene
Sample 1	7.690	0.320	2.152
Sample 2	3.845	0.320	1.076
Sample 3	1.922	0.320	0.538

tions are effective for examining the behaviour of CC in the case of more complicated mixtures.

Table 1 gives the composition of the samples, consisting of a mixture of polynuclear aromatic hydrocarbons (PAHs), prepared from standard reference material SRM 1647 (National Bureau of Standards). The improvement by application of CC, particularly in case of the diluted sample, is considerable.

A typical application of simultaneous correlation chromatography (SCC) is accurate calibration in LC, as is shown in the following experiment. Three different samples, each composed of naphthalene, anthracene and 1,2-benzanthracene, were prepared (Table 2). The concentration of anthracene was kept constant. Anthracene was used as an internal standard to correct for variations in the injected volumes of the different samples. The samples were injected according to a PRBS of 127 clock periods; the starting points of the injection patterns of the different samples were shifted over one-third of the sequence length. The clock period was divided into three subperiods, one for the injection of each sample.

Figure 5 shows the simultaneous correlogram. The peak areas were determined and corrected for systematic errors with the internal standard anthracene. The calibration graph is shown in Figure 6; the calculated correlation coefficient of the linear fit was 0.999 97 – a very good fit.

In principle SCC allows excellent quantification. Deterministic disturbances and drift influence

Table 1 Composition of the PAH sample

Compound	Concentration ($\mu\text{g L}^{-1}$)	Compound	Concentration ($\mu\text{g L}^{-1}$)	Compound	Concentration ($\mu\text{g L}^{-1}$)
Naphthalene	18.0	Fluoranthene	8.08	Benzo[k]fluoranthene	4.02
Acenaphthylene	15.3	Pyrene	7.87	Benzo[a]pyrene	4.24
Acenaphthene	16.8	Benz[a]anthracene	4.02	Benzo[ghi]perylene	3.21
Fluorene	3.94	Chrysene	3.74	Dibenz[a,h]anthracene	2.94
Phenanthrene	4.05	Benzo[b]fluoranthene	4.09	Indeno[1,2,3-cd]pyrene	3.25
Anthracene	2.63

measurement and calibration samples in exactly the same way. Also, the noise-reducing property of CC is maintained. A comparison with sequential calibration can be made by successively performing independent experiments. Each calibration experiment yields an almost perfectly fitting linear calibration plot, but the points for the same concentration, measured successively, are distributed with rather large standard deviations. The bars in Figure 6 indicate the standard deviations of the measurements.

An illustrative example of the application of chemical concentration modulation correlation chromatography is the selective determination of traces of phenol. An electrochemical modulation cell (EMC) and a fluorescence detector are used. This combination, together with a suitable column, is both selective and sensitive to phenol.

Figure 7 shows log-log calibration graphs for conventional loop injection and EMC-CC, respectively. The signal-to-noise enhancement of EMC-CC is a factor of 11 higher at the most, equal to the theoretically predicted value.

Figure 6 1,2-Benzanthracene calibration graph. The bars indicate the confidence interval for successive independent measurements.

(B)

Figure 7 Log-log calibration graphs (solid lines) using loop injection (A), and electrochemical concentration modulation CC (B), both with fluorescence detection. The dashed lines represent the $3\sigma_{\text{baseline noise}}$ curves. Solid symbols were from 63 clock period (cp) injection sequences (11 min); open symbols were from 511 cp sequences (80 min).

Correlation Capillary Zone Electrophoresis (CCZE) Micromachinery

CZE is known for its high detection limits. Correlation techniques, as used in chromatography, can be applied in CZE as well. The goal and basic principles are the same. The main problem is the high demand on the injection system, just as in CC. However, in CCZE the injection system can relatively easily be modified, because CZE is electrically – rather than pressure – driven.

Microchip technology is very well suited for application in CZE systems and particularly in correlation CZE. A high quality injection device on a microchip, connected to a fused silica capillary and particularly usable for correlation CZE, is reported. The speed of separation in a microchip CZE system can be increased due to higher accessible field strengths. Detection is the major problem, because of the smaller channel dimension. The application of

correlation techniques drastically reduces the high detection limit in a modest time.

Countercurrent Chromatography and High Speed Countercurrent Chromatography: Instrumentation

W. D. Conway, School of Pharmacy, State University of New York at Buffalo, Buffalo, NY, USA
Copyright © 2000 Academic Press

Introduction

This article presents a brief overview of the most significant aspects of the history, apparatus, theory and practice of countercurrent chromatography (CCC). CCC is primarily a preparative technique for the isolation and purification of chemicals on a milligram to multigram scale. It has been broadly applied to natural products, pharmaceuticals and other synthetic organic and inorganic chemicals.

What is Countercurrent Chromatography?

Countercurrent chromatography can be broadly characterized as a form of liquid–liquid chromatography (LLC) in which two mutually saturated immiscible liquids are employed. One phase is retained in the chromatograph as a long continuous or segmented stationary bed without the use of an absorptive matrix; the second phase passes through

the stationary bed and is efficiently equilibrated with it by means of either hydrodynamic or turbulent mixing.

In earlier forms of liquid–liquid partition chromatography introduced by Martin and Synge, where one phase is retained in a porous matrix such as diatomaceous earth or cellulose, significant peak tailing is often seen and some analytes are lost by irreversible adsorption on the supporting matrix. In CCC, the stationary phase is retained by gravitational, inertial or capillary forces and adsorption is precluded by construction of the apparatus from polytetrafluoroethylene (PTFE) or other inert, usually polymeric, material. Thus analyte migration in CCC is determined only by its partition coefficient in the two-phase system and peaks are typically quite symmetrical.

CCC differs from countercurrent distribution (CCD) of the type introduced by Craig in the 1940s in that CCD is a discontinuous process based on attainment of partition equilibrium prior to phase transfer, whereas CCC is a continuous dynamic or steady-state process which characterizes all forms of chromatography. Both CCC and CCD may employ the same solvent systems and both achieve separations based on the partition coefficient, but the apparatus

employed and the mathematical treatment of each process are quite different.

The term CCC was coined by analogy to the earlier CCD process and is considered a misnomer by some because, as usually practised, one phase is stationary in the apparatus. However, the terms are justified by the consideration that if the observer resided in either one of the phases, without reference to the stationary apparatus, it would appear that the phases move in countercurrent fashion. Indeed it is possible to actually move both phases in opposite directions but it is then necessary to refer to the process by a redundant term such as 'true' CCC or 'dual' CCC.

Apparatus

Devices that today might be called countercurrent chromatographs were described as early as the 1930s and were used to separate lipophilic substances such as oil-soluble vitamins. However, the modern era of CCC began in the mid-1960s when Yoichiro Ito observed that if two immiscible liquids were placed in opposite halves of a closed helical coil and the coil was rotated on its axis, the liquids flowed into one another in countercurrent fashion (Figure 1). When placed at the initial interface, the individual components of a soluble sample migrate at different rates determined by their relative partition coefficients, K , in the two-phase system. If K , for example, is defined as concentration in the shaded phase divided by concentration in the unshaded phase shown in Figure 1 then components with K higher than unity will migrate to the right, while those with K less than unity will migrate to the left, and those with K equal to one will concentrate in a band at the initial interface. Ito's first CCC apparatus produced true countercurrent flow and was demonstrated to separate soluble mixtures of dyes and proteins in organic-aqueous systems, and also erythrocytes as an example of particulates that partition in two-phase aqueous polymer systems.

When the ends of the coil are opened, the system resembles an Archimedes' screw pump and both phases migrate in the same direction towards what is called the head end of the helix. The actual direction of flow depends on the handedness, left or right, of the coil and its direction of rotation, and will be

towards the right side of the example shown in Figure 1. Now, if either one of the phases is pumped into the right end of the rotating coil in Figure 1, creating head-to-tail flow of the mobile phase, the other phase, attempting to flow towards the head, will be retarded by viscous forces and a very stable equilibrium will be established in which 40 to 60% of the unpumped phase will remain in the column as a stationary phase. Components of a sample introduced as a bolus in the mobile phase will partition between the mobile phase and the stationary phase and be eluted from the coil at the tail end in order of their partition coefficients. This process is exactly analogous to conventional column partition chromatography. As in other forms of chromatography, it is desirable to define the partition coefficient as

$$K = C_s/C_m$$

where C represents concentration in the stationary (C_s) and mobile (C_m) phases, respectively. Then substances with higher partition coefficients will be retained longer in the column.

Instrument geometries

Ito and colleagues have devised many ways in which a helical or modified helical coil of tubing can be rotated with respect to gravitational and inertial fields to achieve good retention of a stationary phase while minimizing band spreading and promoting efficient mass transfer of solutes. A few will be described here based on their historical or practical significance.

Horizontal flow-through coil planet centrifuge The behaviour just described in 'Apparatus' above is that produced by the horizontal flow through coil planet centrifuge (HFTCPC), first described in the late 1970s. Its characteristic motion is shown in Figure 2B. The device typically consisted of several single-layer helices formed by winding PTFE tubing, measuring a few millimetres internal diameter, on rods about 12 mm in diameter and about 40 cm long, and mounting several of these, connected in series, on a cylindrical column holder. The holder was geared to rotate on its own axis, twice in each orbit, as it revolved around a central or solar shaft. Separations

Figure 1 Countercurrent migration of immiscible liquids in a rotating helical tube with closed ends.

typically required 10 or more hours. The HFTCCP was not a commercial success at the time, but the configuration has reappeared as an optional column configuration in some recently described high-speed CCC apparatus.

Droplet countercurrent chromatography Earlier in the 1970s, Ito and colleagues described a simple non-centrifugal CCC technique called droplet countercurrent chromatography (DCCC). As illustrated in Figure 2A with a mobile heavy phase, it consisted of some 300 glass tubes, 1.8 mm i.d., connected in series with narrow-bore PTFE tubing. Either phase could be mobile. The technique, however, was limited to solvent systems that formed droplets. It relied on gravity for phase separation and was very slow, requiring 60 or more hours for a typical separation. In spite of these limitations, it was successfully marketed and was widely employed by natural product chemists; the technique is still available today.

Multilayer coil planet centrifuge The multilayer coil planet centrifuge (MLCPC) described by Ito and colleagues in the early 1980s is one of the most versatile and widely used instruments. Versions of it are available worldwide from several companies. It is shown schematically in Figure 2C, where the helical coil is seen to consist of several layers of tubing wound concentrically on the column holder, which again

rotates twice on its axis in each orbit. The forcefield acting on the coil is quite different here from that obtained in the eccentric configuration (Figure 2B) just described. The orbital radius, R , is typically about 10 cm and the orbital frequency is typically about 800 r.p.m. The coil consists of about 10 to 16 layers of PTFE tubing, 2–3 mm i.d., wound on a spool 5 or more cm wide, starting at a radius r of about 5 cm (half of R) to a maximum of 8 or 9 cm. The winding is not actually a spiral as shown in Figure 2C, but consists of the multiple back-and-forth helical layers typically obtained by winding flexible tubing on a spool. A spool 5 cm wide and 17 cm in diameter might contain about 130 m of tubing 1.68 cm with i.d., with a total volume of about 300 mL.

The forcefield obtained in the MLCPC produces a unique mixing pattern in which the phases in the outward portions of the coil are separated as concentric layers of moving phase and stationary phase, the heavier layer being outwardly directed. On the other hand, in a segment of the inner portion of the coil, comprising about one-third of the coil volume, the phases are quite vigorously mixed. This dynamic mixing pattern is independent of the mobile phase flow rate and since the entire coil rotates through the mixing zone some 13 times each second, very good solute mass transfer is obtained. Typical separations are obtained in from 2 to 6 hours in 300-mL coils and

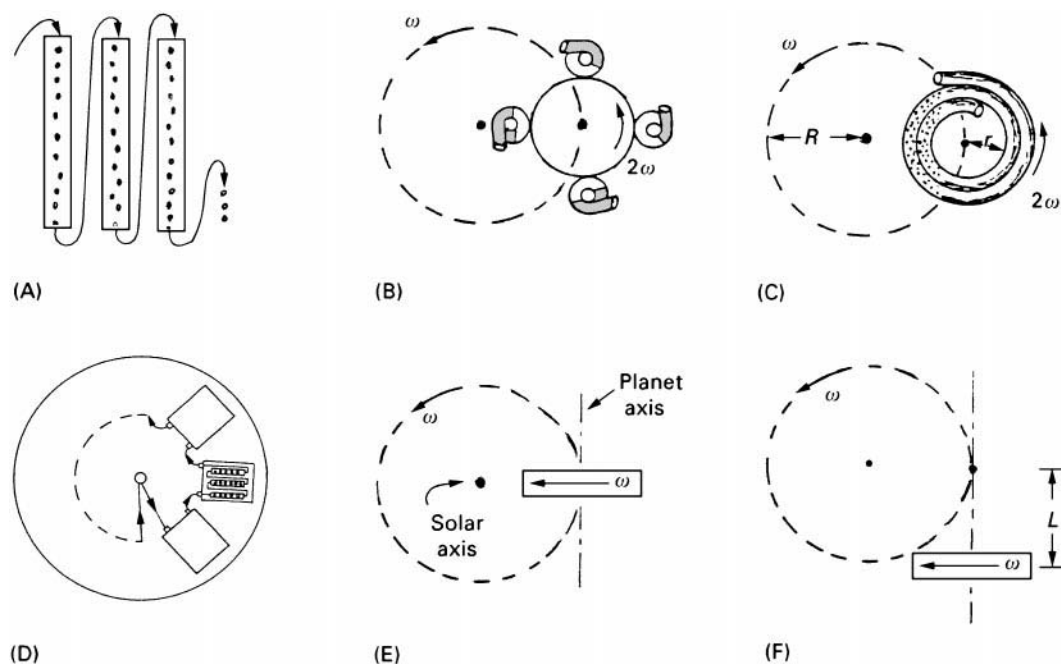

Figure 2 Schematic illustrations of (A) droplet countercurrent chromatography, (B) the horizontal flow-through coil planet centrifuge, (C) the multilayer coil planet centrifuge, (D) the centrifugal droplet countercurrent chromatograph or centrifugal partition chromatograph, (E) the cross-axis CCC and (F) the laterally displaced cross-axis CCC.

much faster separations are obtained, with some loss of resolution, in smaller coils. Resolution is enhanced in the MLCPC by its very high retention of stationary phase, often 80% of the coil volume. A unique feature of all Ito-style CCC apparatus developed since about 1980 is the lack of a rotating seal. Because of the gear systems employed to rotate the columns, influent and effluent streams convey liquids from the instrument exterior to the rotating coil using a so-called antitwisting scheme, which does not involve a rotating seal, thereby avoiding leakage, local heating and contamination associated with such seals. Apparatus is available containing one, two or three spools on a single rotor and in some instruments multiple coils are available in a single spool. These may be operated independently or in series making the MLCPC one of the most versatile types of CCC apparatus.

Centrifugal partition chromatography One of the few types of modern CCC instrumentation developed outside Ito's laboratory was designed by Murayama and colleagues at Sanki Engineering (Japan) and was introduced in the early 1980s. It was designated simply as a centrifugal countercurrent chromatograph and today is usually referred to as a centrifugal partition chromatograph (CPC). Some confusion results from use of the CPC acronym since it is widely used to represent the coil planet centrifuge in Ito-style chromatographs. Conceptually the technique has been described as centrifugal droplet countercurrent chromatography (CDCCC, see Figure 2D). This description is based on the early models of the apparatus, which consisted of a series of cartridges of fluoroplastic in which a series of drilled cylindrical chambers were connected by small grooves, superficially resembling the larger gravitational DCCC apparatus. Cartridges were connected in series and spun at high speed in a rotor, to which inlet and outlet lines were connected through rotating seals. The apparatus could be filled with one phase and, when rotated, the other phase could be pumped through. Either the heavy (descending mode) or lighter (ascending mode) phase could be pumped through. In later versions of the apparatus, the chambers and passageways are formed by etching them in the surface of a sandwiched stack of rotor plates. Although described as a form of droplet chromatograph, actual droplet formation may not play a major role in mass transfer since many solvent systems function well in the CPC that do not form droplets in the gravitational apparatus. The apparatus is sometimes characterized as a static system, as opposed to a dynamic system, since mixing and mass transfer are dependent on the chamber design and on the mobile phase flow rate; mixing

efficiency increases with increasing flow rate. An advantage of the CPC is that units of very large volume can be constructed since it is not subject to the problems of vibration associated with coil planet centrifuges.

Cross axis and laterally displaced cross axis CCC Since about 1989, Ito and colleagues have published many papers on chromatographs described as cross-axis, X-axis or laterally displaced cross-axis chromatographs (XL). It is difficult to illustrate these without three-dimensional models, but an attempt has been made to show them schematically in Figure 2E and F. In the X-axis unit, the coil axis is simply tilted 90° , or crossed with respect to the solar axis. In the earlier CCC units (Figure 2B and C), these axes are parallel. In the XL unit, the coil is further displaced a distance L along the planet axis from the central X position, where the solar axis lies in the rotational plane of the coil.

The effect of tilting the coil is to introduce a third dimensional component to the forcefield. In the parallel shaft units (Figure 2B and C), the forcefield vectors all lie in the two-dimensional plane of rotation of the coil. But the X and XL displacements introduce a force vector in the vertical or solar axis plane. These changes have a significant effect in improving phase mixing phenomena and column efficiency. This is particularly important for viscous solvent systems such as aqueous two-phase polymer systems of the polyethylene glycol-salt and polyethylene glycol-dextran type. These systems function poorly in the HFTCPC and even less well in the MLCPC systems. The aqueous two-phase polymer systems are important for the separation of proteins, enzymes and biological particulates. Unfortunately, the X and XL chromatographs are mechanically more complex than previous instruments and are not yet commercially available.

Monitors

Many CCC technicians simply collect fractions and monitor their composition by thin-layer chromatography (TLC). The column effluent can often be continuously monitored by UV absorption spectrophotometry. The main interference with monitoring is the tendency for droplets of stationary phase carried into the flow cell to cause noise spikes or to adhere to the cell windows. The problem is minimized by using a flow cell with a vertical flow path and by flowing a lighter mobile phase in the downward direction, and a heavier mobile phase in the upward direction. This tends to flush droplets of stationary phase through the cell quickly. Other methods used include warming the column effluent

just before it enters the monitor cell, or bleeding a stream of a miscible solvent, such as methanol, into the column effluent. Another approach uses a diode array detector to monitor the droplet noise in an area of the spectrum where the analyte does not absorb, such as the visible region, and to subtract the noise, on line, from the absorbance at the wavelength used for monitoring. Fluorescence may be used for monitoring and presents similar problems to absorptiometry.

Evaporative light-scattering detectors are excellent for monitoring compounds that lack chromophores and work with other compounds as well. The volatile solvents employed in CCC are quite compatible with evaporative light scattering as long as no non-volatile constituents like salts or buffers are incorporated into the solvent system. Several publications have appeared linking CCC with mass spectrometry and with nuclear magnetic resonance (NMR).

Theory

Countercurrent chromatography (CCC) is usually done by first filling the column at rest with stationary phase, then starting rotation and pumping in the mobile phase at a constant flow rate. The sample may be introduced at the head of the mobile phase stream or later. As it makes its initial pass through the coil, the mobile phase stream will displace a volume, V_{CO} , of stationary phase, which will be carried over into the collection vessel. Subsequently, the phase-volume ratio in the column is usually stable. This carryover volume is then a measure of the mobile-phase volume V_m and the stationary phase volume, V_s , can be estimated by subtracting V_{CO} from the known column volume V_C :

$$V_s = V_C - V_m = V_C - V_{CO}$$

Measuring the retention time of an unretained solute provides an alternative means for estimating V_m .

Because V_s is known in CCC, the chromatogram can be advantageously described in terms of the concentration partition coefficient K (defined earlier as $K = C_s/C_m$) of the analyte, rather than the quantity

distribution coefficient or retention factor, k , used in other forms of chromatography.

The countercurrent chromatogram can be succinctly perceived visually in terms of K and the fact that an analyte with $K = 1$ will *always* elute with a retention volume equal to the column volume, V_C . The column volume, or the time corresponding to it, is the focal point of the countercurrent chromatogram and the emergence of $K = 1$ at this point is independent of the phase volume ratio. Of course, analytes with $K = 0$ will not be retained and will emerge with the mobile phase front. Other analytes with integral values of K will elute at multiples of the stationary phase volume, or time, beyond $K = 1$ and the position of intermediate values can be determined by linear interpolation. Therefore, **Figure 3** presents a completely general picture of a countercurrent chromatogram of analytes with $K = 0, 1, 2, 3$ and it is apparent that the elution pattern is described by the equation:

$$V_R = V_m + KV_s$$

where V_R is the analyte retention volume.

Since flow rate is usually constant, a time scale can be added or imagined. For instance if **Figure 3** were obtained with a 300-mL column at a flow rate of 3 mL per min, $K = 1$ would emerge at 100 min and $K = 0$ at about 30 min. V_s then corresponds to 70 min and $K = 3$ emerges at about 240 min. An analyte with $K = 1.5$ could be expected to emerge at about 135 min. An example showing the separation of a series of phenylalkanols is shown in **Figure 4**.

Separation of the closely related compounds pacilitaxel and cephalomantine by a form of recycling CCC is shown in **Figure 5**. In this approach, the peak containing the mixture was separated from other extraneous material in the first cycle through the CCC by shunting the effluent containing it into a holding tube of the same diameter tubing used in the CCC column. The shunt was then reconnected to the CCC inlet and the material chromatographed a second time, and the shunting process was again repeated to obtain the separation shown in **Figure 5**.

Figure 3 A generalized countercurrent chromatogram for solutes with partition coefficients, K , of 0, 1, 2 and 3.

Figure 4 CCC separation of a mixture of 10 μ L each of benzyl alcohol, 2-phenylethanol and 3-phenylpropanol on a 24-m coil of 1.68-mm PTFE, 56 ml volume using heptane as stationary phase and a mobile phase of 25% 2-propanol in water flowing at 4 mL min^{-1} . Reproduced from Conway WD, Buchert EL, Sarlo AM and Chan CW (1998) with permission from Marcel Dekker.

Resolution

The effect of V_s on analyte resolution is also apparent from Figure 3. Experimental parameters that alter V_s , such as flow rate or rotational speed, will not affect the $K = 1$ point. But as flow rate is increased, more stationary phase will be carried over and the V_m distance will increase towards the right, decreasing V_s . The V_s distances beyond $K = 1$ will move to the left, thereby decreasing resolution between the peaks. In the extreme case of high flow rate, all stationary

phase will be forced from the column and all peaks will converge and be eluted at the column volume, or $K = 1$ point, which emphasizes the importance of the column volume or $K = 1$ point in the countercurrent chromatogram.

Direct measurement of the resolution, R_s , of two peaks on a chromatogram is based on the definition:

$$R_s = \frac{V_2 - V_1}{0.5(W_2 + W_1)}$$

Figure 5 Separation of paclitaxel (1) and cephalomarine (2) by recycling CCC using the solvent system hexane/ethyl acetate/methanol/water – 6 : 4 : 5 : 5 (v/v/v/v) and a 230-mL column of 1.6 mm PTFE with a mobile aqueous phase flowing at 1.7 mL min^{-1} . Reproduced from Du Q-Z, Ke C-Q and Ito Y (1998) with permission from Marcel Dekker.

where V_2 and V_1 are the retention volumes of the second and first peaks to emerge and W_2 and W_1 are their 4-sigma base widths measured in the same units as V_2 and V_1 . With this definition an R_s value of 1.5 represents baseline resolution.

The contribution of other factors to resolution in CCC is summarized in the following general resolution equation:

$$R_s = 0.25(\alpha - 1)N^{0.5} \left[\frac{K_1}{0.5K_1(\alpha + 1) + (1 - S_F)/S_F} \right]$$

where K_1 is the partition coefficient of the first of a pair of chromatographic peaks to emerge and α , N and S_F are the separation factor, the column or coil efficiency, and the fraction of the column volume occupied by stationary phase, respectively.

The separation factor is defined as:

$$\alpha = K_2/K_1$$

where K_2 is the partition coefficient of the second peak of the pair to emerge and is always calculated to be greater than 1.

Efficiency in theoretical plates is defined in terms of the peak base width as:

$$N = 16 \left(\frac{V_R}{W_1} \right)^2$$

where W_1 is the 4-sigma base width of the peak and is measured in the same units as V_R .

S_F , the stationary phase fraction is:

$$S_F = V_s/V_C$$

and its expression in the denominator of the resolution equation is seen to represent the phase-volume ratio:

$$(1 - S_F)/S_F = V_m/V_s$$

The resolution equation confirms the visual observation from Figure 3 that increasing V_s will increase resolution.

The three terms in the resolution equation are usually called the separation factor term, the efficiency term and the large term in brackets is the partition coefficient term. Each can be evaluated independently from the countercurrent chromatogram.

The α term The separation factor term depends on the selectivity of the solvent system for one analyte versus another. It is often the dominant term leading to separation but it is not predictable and must be

determined by an empirical examination of various solvent systems. The search is best conducted by non-CCC means of measuring partition coefficients, such as high performance liquid chromatography (HPLC) or TLC or by using small-volume CCC columns. An advantage of CCC is that a very large number of solvent systems is available.

The efficiency term The square root dependence of N indicates that doubling resolution will require a four-fold increase in column length, which is often not practical because of the resultant increase in backpressure and separation time. CCC provides only a modest number of theoretical plates, usually in the range of 300 to 1000, unless narrow-bore columns are employed at low flow rate. It is comparable to flash-column chromatography in terms of N . However, resolution in CCC is frequently much better than might therefore be expected because of the greater contribution of α and because of the very high S_F , typically 0.7 or more, obtained with some solvent systems.

The partition coefficient term Changing the polarity of the solvent system to increase K_1 will increase resolution, but the benefit rapidly diminishes as K_1 increases. The magnitude of the effect depends on S_F , but when S_F is 0.4, 80% of the effect of increasing K_1 will be obtained when K_1 reaches about 4, at which retention time will be quite long, especially for K_2 .

If S_F is 0.8, 80% of the effect of increasing K will be obtained when K_1 is about 1, so it is more practical to arrange conditions so that S_F is as high as possible and then adjust K of the component of interest to the range of about 1 to 2.

Solvent Systems

A very wide range of two-phase solvent systems can be used in CCC. These include an aqueous phase with solvents ranging in polarity from hexane through chloroform, ethyl acetate and n-butanol. Partition coefficients can be modified by mixing the organic solvents with each other or by adding a miscible solvent such as methanol, 2-propanol or acetonitrile to the system. While these dissolve primarily in the aqueous phase, they partially dissolve in the organic phase, making the system more miscible and shifting the analyte partition coefficient towards 1. When systems become too miscible, the stationary phase is poorly retained. An example is 2-butanol, which when saturated contains about 40% water by weight. Some solvent systems that have been extensively employed in CCC are given in Table 1.

Table 1 Representative solvent systems for CCC

1. Hexane/ethyl acetate/methanol/water – 3 : 7 : 5 : 5 (v/v/v/v)
2. Chloroform/methanol/water – 7 : 13 : 8 (v/v/v)
3. Chloroform/methanol/water – 4 : 4 : 3 (v/v/v)
4. Chloroform/methanol/water – 5 : 5 : 3 (v/v/v)
5. Hexane/methanol – any ratio
6. Hexane/acetonitrile – any ratio
7. n-Butanol/water – any ratio

The first system given in Table 1 is useful for lipophilic materials; the chloroform systems are widely used for solutes of intermediate polarity and n-butanol/water is one of the most polar systems available. Systems 5 and 6 (Table 1) are non-aqueous systems and are particularly useful for very lipophilic materials with no solubility in water. Prior to its use in the CCC, the solvent system is always shaken in a separation funnel and allowed to separate to ensure mutual saturation of the two phases. Solvent systems are covered extensively in all of the reference works listed in Further Reading and are only discussed here very briefly.

Screening solvent systems

To use CCC successfully it is necessary to empirically search for suitable solvent systems using non-CCC methods initially. The first goal is to find a system that provides a K of 1 to 2 and that provides good sample solubility in *both* phases. This latter point is important because sample capacity will be limited by the phase in which the sample is least soluble. Two approaches to screening K values will be described here briefly.

Using TLC Prepare a small amount of the proposed bi-phasic solvent system and partition some sample between about 200 μL of each phase. Spot 20 μL of each of the phases side by side on a TLC plate and develop with a suitable TLC system. Visual examination, or better, scanning with a TLC densitometer, of the separated spots for the two phases will allow a judgement to be made as to which of the components have K values in the neighbourhood of 1.

Using HPLC Dissolve a small amount of sample in about 500 μL of aqueous phase. Chromatograph 20 μL in a suitable HPLC system. Then equilibrate the aqueous solution with the same volume of non-aqueous phase, discard the non-aqueous extract and again chromatograph 20 μL of the aqueous phase. From the respective peak heights, the partition coefficients in the CCC solvent system can be calculated.

Since CCC retention depends only on K , using the equation for V_R , or simply referring to Figure 3, the expected retention times of the sample components can be calculated.

Other Chromatographic Approaches

Substances with high K values that are not eluted, will be to some extent separated along the column and can be recovered by stopping the apparatus and pumping out the column contents. An alternative approach is to switch phases without stopping the chromatography. In the MLCPC, the appropriate directions for pumping the phases is head to tail for the heavy phase and tail to head for the lighter phase, so this approach involves switching the column inlet as well. For the CDCCC, the corresponding directions are downward for heavy phase and upward for lighter phase.

Yet another approach to manipulating CCC is to fill the column initially with a non-equilibrium ratio of phase volumes by simultaneously filling both phases at once. Retention of particular K values can be enhanced or diminished by choosing the appropriate phase-volume ratio. Gradients can also be used for a number of systems, particularly where the composition of the stationary phase changes very little as the polarity of the mobile phase is changed.

For acidic and basic substances, adjustment of pH or use of a pH gradient can be useful. The range of pH is not a limitation as far as the apparatus is concerned. Ion-pair formation and use of liquid-ion exchangers can also be exploited, and various chelating agents have been used for the separation of metals, particularly rare earths. Optical resolutions have been achieved by addition of chiral selectors predominantly soluble in one of the phases to the solvent system.

The above examples indicate a few of the many ways in which CCC apparatus can be manipulated to achieve separations by means other than straightforward chromatography.

pH-Zone Refining

The technique of pH-zone-refining CCC primarily developed by Weisz and Scher in collaboration with Ito, deserves special mention because it is unique to CCC. It is applicable to organic acids and bases and is clearly the technique of choice for obtaining highly purified dyes and samples of the impurities contained therein.

For a very brief explanation it is convenient to view the technique as a kind of two-phase acid–base titration carried out in a CCC column. To illustrate this, imagine a series of aromatic carboxylic acids that

differ slightly in pK_a as well as lipophilicity. Typically a simple solvent system such as methyl t-butyl ether (MTBE) and water is mutually saturated and the phases put in separate containers. The organic phase is acidified with trifluoroacetic acid (TFA) and the column is filled with it as the stationary phase. In practice, either phase can serve as the stationary phase but the organic phase is chosen in this example. The sample of mixed acids is dissolved, or suspended if incompletely soluble, in a portion of the acidified stationary phase and introduced at the column inlet. The aqueous phase is made basic with ammonia and pumped into the rotating column. The acidified sample will dissolve in a relatively small zone of acidified MTBE at the column inlet and as the basic mobile aqueous phase is introduced it will neutralize portions of the sample, which will then be extracted into the aqueous phase. However, on moving down the column, the zone will encounter more TFA, undergo re-acidification and again be transferred to the stationary organic phase. This neutralization and transfer will proceed, as in a titration, first with the acid of lowest pK_a , modified also by the lipophilicity of the particular acid, those with lowest pK_a and lowest lipophilicity migrating fastest.

Monitoring the eluent by UV absorption is usually not informative, but monitoring the pH shows a series of broad steps of increasing pH containing very pure samples of the individual acids with

impurities concentrated at the interfaces between the zones. Bases can be separated in a similar fashion. This technique provides a sample capacity of several grams.

An example showing the separation of two isomeric nitrochloromethoxybenzoic acids by pH-zone refining is presented in Figure 6. Monitoring the UV absorbance of the effluent yields only a flat trace, which does not indicate the separation. However, the effluent pH shows sharp steps at the start and end of the component zones. Using a 310 mL-column and a sample size of 20 g, the separation yielded 9 g of the pure 2-nitro compound, 5.3 g of the 6-nitro isomer and 2 g of a mixture of the two.

Conclusion

Modern CCC is a novel form of preparative LLC that offers more versatility in the choice of solvents, ranging from very lipophilic to moderately polar organic or aqueous systems. It provides predictable retention behaviour and complete recovery of sample since retention depends only on the solute partition coefficient and adsorption is precluded by the inert nature of the apparatus. Its separation capability is further enhanced by various technical manipulations of solvent composition and flow during chromatography, which cannot be reproduced in other types of chromatography. CCC has been widely employed by

Figure 6 Separation of 2- and 6-nitro-4-chloro-3-methoxybenzoic acids by pH-zone-refining CCC. Initial stationary phase is 0.3% (12 mM) trifluoroacetic acid in the upper organic phase of a mixture of methyl t-butyl ether/acetonitrile/water – 4 : 1 : 5 (v/v/v). The mobile phase was 0.8% (100 mM) ammonia in the lower aqueous phase pumped at 3 mL min⁻¹. The column volume is 310 mL. Reproduced from Dudding T, Mekonnen B, Ito Y and Ziffer H (1998) with permission from Marcel Dekker.

natural product chemists for the isolation and purification of unstable bioactive materials from complex matrices. The technique deserves more attention from analytical chemists confronted with the separation of complex mixtures, synthetic chemists facing purification of non-crystalline products, diastereomers or optical resolution of racemates, and physical chemists seeking new approaches to the study of solvent interactions or the measurement of chemical properties such as partition coefficients or dissociation constants. Continuing study of new applications of CCC in several laboratories, as well as the commercial development of more reliable and user-friendly apparatus, promises to extend the use of CCC in the foreseeable future.

CCC Literature

References to CCC applications are found throughout the analytical and natural product literature and in the monographs cited below. A large number of references are found in *Journal of Chromatography* and in *Journal of Liquid Chromatography and Related Techniques*, many of which are collected in periodic special issues of these journals, the latest of which contains over 20 articles. A list of earlier special issues can be found in Conway (1995).

Detectors: Laser Light Scattering

R. P. W. Scott, Avon, CT, USA

Copyright © 2000 Academic Press

Introduction

There are two types of light scattering detectors used in liquid chromatography, the evaporative light scattering detector and the liquid light scattering detector. The former evaporates the solvent from the column eluent in a gas stream and measures the light scattered by the residual solute particles; this type of detector is

described elsewhere in this encyclopedia. The second, the liquid light scattering detector, senses the actual solute molecules themselves by light scattering measurements. Liquids containing large molecules such as synthetic polymers, biopolymers, e.g. polypeptides, proteins and polysaccharides, scatter light and, providing the incident light is strong enough, the scattered light can be sensed and used to detect the presence of the solute. In practice the column eluent is allowed to flow through a cell through which passes a high intensity beam of light. The light source is usually a parallel beam laser (light amplification by

the stimulated emission of radiation) that generates light at an appropriate wavelength for measurement. The scattered light is viewed at a specific angle by a photosensor, the output of which is electronically modified and passed to a potentiometric recorder or, more probably, to a computer data acquisition system.

Alternative Light Scattering Detectors

Two basic types of liquid light scattering detectors have been developed and made commercially available, each having its unique advantages and disadvantages. The two forms of the detector: the low angle laser light scattering (LALLS) detector and the multiple angle laser light scattering (MALLS) detector. Both devices are used extensively in polymer analysis. The multiple angle laser light scattering detector is somewhat more versatile and, under the right conditions, can also provide molecular dimensions as well as molecular masses. As would be expected from its name, in the low angle laser light scattering detector, the intensity of the scattered light is measured at a very small angle to the path of the incident light (virtually 0°). Under these conditions, the signal can also receive light that has been scattered by contaminating particulate matter that is always present in the eluent. This extra light source can contribute considerable noise to the signal, which, in turn, will reduce the detector sensitivity. Discussions on these aspects of the different detectors have been given by, P.J. Wyatt and some early experimental results reported by D.T. Phillips.

From the work of Rayleigh, the ratio of the intensity of the light scattered at an angle (ϕ), (I_ϕ) to the intensity of the incident light (I_0), is given by the following equation:

$$\frac{I_\phi}{I_0} = \alpha \omega R_\phi \quad [1]$$

where α is the attenuation constant, ω is a function of the refractive index, and R_ϕ is Rayleigh's constant.

Thus, the Rayleigh constant can be extracted from the above equation giving:

$$R_\phi = \frac{I_\phi}{\alpha \omega I_0} \quad [2]$$

Now, the relative molecular mass (M_r) of the solute that is scattering the light is, in turn, related to the Rayleigh factor by the following expression:

$$M_r = \frac{R_\phi}{c(K - 2A_2R_\phi)} \quad [3]$$

where c is the concentration of the solute, A_2 is a function of polymer-polymer interactions, and K is the polymer optical constant.

Substituting for R_ϕ in eqns [3] from [2]:

$$M_r = \frac{I_\phi / \alpha \omega I_0}{c(K - 2B_2(I_\phi / \alpha \omega I_0))} = \frac{I_0}{c(\alpha \omega I_0 K - 2B_2 I_\phi)} \quad [4]$$

where:

$$K = \frac{2\pi^2 \eta^2}{\lambda^4 N (d\eta/dc)^2} \quad [5]$$

and η is the solvent refractive index, λ is the wavelength of the light in vacuum, and N is the Avogadro number.

Eqn [4] gives the basic relationship between the relative molecular mass of the scattering material, the intensity of the scattered light and the physical properties of the materials and equipment that are being employed. Unfortunately, eqn [4], includes a number of constants, the magnitude of which can be extremely difficult, if not impossible, to determine accurately. Consequently, an alternative procedure must be adopted to handle the data provided by the intensity of the scattered light and the angle at which it is measured. In practice, a simple graphical procedure is adopted to determine the relative molecular mass of the solute that avoids the need to determine all the pertinent constants.

Rearranging eqn [3]:

$$\frac{1}{M_r} = \frac{c(K - 2A_2R_\phi)}{R_\phi} = \frac{cK}{R_\phi} - 2cA_2$$

or:

$$\frac{cK}{R_\phi} = 2cA_2 + \frac{1}{M_r} \quad [6]$$

This arrangement provides a convenient linear relationship between the important variables that can be measured. Thus c , K and R_ϕ are either known or can all be calculated from known data and calibration light scattering measurements; consequently, by plotting (cK/R_ϕ) against c a straight line will be produced with the intercept being ($1/M_r$).

It follows that a value for the relative molecular mass of the eluted polymer can also be estimated.

Low Angle Laser Light Scattering Detector

The optical system of a commercial low angle laser light scattering detector is shown diagrammatically in

Figure 1 Optical diagram of a low angle laser light scattering detector (LALLS). (Reproduced by permission of LDC Analytical, Thermo Instruments Corporation.)

Figure 1. Owing to the length of the laser light generator, the instrument can become extremely bulky so certain optical space-saving arrangements need to be adopted. To conserve space and make the optical system compact, a folding prism system is used that allows the optical system to be contained to a reasonable size and still accommodate the length of the laser generator.

Light from the laser source passes through diverging lens, then through a chopper, and finally through the folding prism. The laser beam then passes out of the folding prism, through some measuring attenuators, then through a calibrating attenuator shutter and finally through the cell. Between the cell and the relay lens is placed an annular mask that only allows light scattered in the cell at a low angle to pass to the relay lens. Between the annular shutter and the relay lens is placed a safety attenuator that ensures that none of the laser light can reach the photomultiplier, which would cause severe damage. The scattered light is focused through a field stop onto the forward detector lens. For convenience, a prism is placed between the field stop and the forward detector lens, allowing the scattered light to be viewed through a microscope. A filter holder and an analyser/polarizer is placed between the forward detector lens and the rear detector lens. Finally, the scattered

light is focused through the sensor aperture on to an opal diffuser that spreads the scattered light through a red filter and onto the sensor plate of a photomultiplier. The device is conveniently operated in series with a refractive index detector in order to coincidentally measure the refractive index of the eluent.

It is clear from eqn [5] that in order to calculate K the refractive index of the solute must also be known. It is also seen from eqn [4] that an estimate of the relative molecular mass of a solute can be obtained from the intercept ($1/M_r$) of the graph relating (cK/R_ϕ) to the solute concentration c , as shown in **Figure 2**. The concentration is usually determined from the output of the refractive index detector from prior calibration.

The overall sensitivity (minimum detectable concentration) of the detector appears to be very similar to that of the refractive index detector (i.e. about $1 \times 10^{-6} \text{ g mL}^{-1}$ at a signal-to-noise ratio of 2) and would seem to have about the same linearity and linearity range (i.e. $0.97 > r > 1.03$ over a concentration range of 2–3 orders of magnitude). However, the most important characteristic of this detector is not its propensity for accurate quantitative analysis but its proficiency in providing relative molecular mass for extremely large molecules.

Figure 2 Determination of relative molecular mass from low angle light scattering measurements.

An example of the use of the low angle laser light scattering detector to monitor the separation of bovine serum albumin monomer, anti-bovine serum albumin and bovine serum albumin complex is shown in **Figure 3**. The relative molecular masses of the three components as measured by the LALLS detector were, bovine serum albumin monomer, 66 700 (literature value 66 000), anti-bovine serum albumin, 150 800 (literature value 150 000) and the bovine serum albumin complex 297 300. It is seen that fairly accurate estimates of relative molecular mass can be achieved by this type of detector. The column used was the G 3000 SWXL and the mobile phase a phosphate saline solution buffered at pH 7.1–7.2. The flow rate was 0.4 mL min⁻¹ and the sample volume was 100 µL. The UV detector was operated at 280 nm.

Multiple Angle Laser Light Scattering (MALLS) Detector

The multiple angle laser light scattering detector differs significantly from the low angle laser light scattering detector in that scattering measurements with this device are made at a number of different angles, none of which are close to the incident light. This reduces, in fact almost eliminates, the problem associated with scattering from particulate contaminants in the sample. In addition, measuring the scattered light simultaneously at a number of different angles allows the root-mean-square (rms) of the molecular radius $\langle r^2 \rangle^{1/2}$ of the polymer to be calculated in addition to its relative molecular mass.

Figure 3 Separation of anti-bovine serum albumin and some bovine serum albumin complexes. Peaks: 1, anti-bovine serum albumin; 2, bovine serum albumin monomer; 3, bovine serum albumin complex. (Reproduced by permission of Qian RL, Mhatre R and Krull IS, 1997.)

The relationship that is used to process the data from this detector is as follows:

$$\frac{cK}{R_\phi} = a\langle r^2 \rangle^{1/2} \sin(\phi)^2 + bM_r \quad [7]$$

where the symbols have the meanings previously defined.

In fact, detailed examination of the theory of light scattering at larger angles can provide explicit functions for the constants a and b . However, in practice, values for these constants are usually obtained from measurements made on calibrating substances of known relative molecular mass and molecular radii. Furthermore, in any practical device each photocell (used to sense the light at the different scattered angles) will not have precisely the same response to light of low level intensity. Consequently, calibration

procedures are also necessary to take the different response of the individual sensors into account to provide appropriate correction factors.

The number of different angles at which the scattered light is measured differs widely with different instruments, and commercial equipment that measure the intensity of the scattered light at as many as 16 different angles are available. It is clear that the greater the number of data points taken at different angles, the more precise and accurate the results will be. A diagram of a relatively simple commercial (MALLS) detection system which measures the light scattered at only three different angles is shown in Figure 4. The device is very simple – it contains no mirrors, prisms or moving parts and is designed such that the light paths are direct and there is no need to use an optically ‘folded’ light system. It is seen Figure 4 that light passes from the laser (wavelength 690 nm) directly through a sensor cell. The scattered light passes from the centre of the cell through three narrow channels to three different photocells, set at 45° and 90° and 135° to the incident light. Thus, scattered light is continuously sampled at three different angles during the passage of the solute through the cell.

A continuous analogue output is provided from the 90° sensor for monitoring purposes and, in the particular system described, all the sensors are sampled every 2 s. The relative molecular mass range is claimed to extend from 10^3 to 10^6 and the rms radii from 10 to 50 nm. The total cell volume appears to be about 3 μL and the scattering volume is as little as 0.02 μL . The detector has a sensitivity, which is defined by the manufacturers, in terms of the minimum detectable excess Rayleigh ratio of $5 \times 10^{-8} \text{ cm}^{-1}$. This sensitivity is difficult to translate into normal concentration units but appears to be very similar to that of the refractive index detector, which is

Figure 4 The multiple angle laser light scattering detector (miniDawn®). (Reproduced by permission of Wyatt Technology Corporation.)

Figure 5 Calibration curves for the multi angle light scattering detector. Intercept (I) gives a value for the relative molecular mass; slope (S) give a value for the rms molecular radius.

equivalent to a minimum detectable concentration of about $10^{-6} \text{ g mL}^{-1}$.

The relationship between the intensity of the scattered light, the scattering angle and the molecular properties, are given by the following equation:

$$\frac{cK}{R_\phi} = 2cA_2 + \frac{1}{M_r P(\phi)}$$

where $P(\phi)$ describes the dependence of the scattered light on the angle of scatter and the other symbols have the meanings previously attributed to them.

In fact, the relationship between the angle of scattering, θ , the relative molecular mass and the rms molecular radius of the solute is obtained using eqn [7]. Employing appropriate reference materials, graphs of the form shown in Figure 5 can be constructed to evaluate constants a and b and thus permit the measurement of the relative molecular mass and molecular radius of unknown substances. This detecting system can be extremely valuable when dealing with unknown biopolymers where little or no evidence is available as to their mass or size and the use of the mass spectrometer is prohibited by either their mass or thermal instability.

The separation of bovine serum albumin (BSA), lysozyme, bradykinin and leucine enkephalin monitored by the multiangle light scattering detector and the refractive index detector in Figure 6. The high response of the multiangle light scattering detector to the high relative molecular mass BSA is clearly demonstrated. The relative molecular mass measurements made on the solutes are shown in

Figure 6 Chromatograms obtained simultaneously from the multiangle light scattering detector (A) and the refractive index detector (B).

Table 1 Peptide and protein mass values from the multiangle light scattering detector

Peak	Solute	M_r (sequencing)	M_r (measured)
1	BSA	67 000	64 300 \pm 700
2	Lysozyme	14 300	14 600 \pm 300
3	Bradykinin	1 060	1 090 \pm 10
4	Leucine-enkephalin	556	592 \pm 6

Table 1, which also includes relative molecular mass data obtained from sequencing the solutes.

It is seen that fairly accurate values for relative molecular mass can be obtained for the larger

molecules, which can be extremely useful when dealing with completely unknown biopolymers. The errors involved are significantly greater for the materials of smaller relative molecular mass because the response (the amount of light scattered) is much less, and the output signal is much closer to the noise level of the sensing system. Further discussion of these types of detector are furnished in references provided in the Further Reading section.

Hydrodynamic Chromatography

Summary

Hydrodynamic chromatography (HDC) is one of the many techniques for particle size determination in the micron range. It has some similarities with size exclusion chromatography and field flow fractionation, but needs only one phase and one field. The main advantages are the separation of species according to size only, rapidity of measurement in the untreated medium and ease of operation of equipment. Variation in operating parameters allows a considerable

range of possible applications. Disadvantages are low resolution, necessity for peak dispersion correction and calibration for signal intensity according to size. It has many applications in latex production and quality control.

Definition and General Features

Definitions

Particles may be separated according to their size by several techniques: HDC is one of them. This interesting rapid method (about 10 min) separates and sizes solutes or particulates in the micron range (0.030-60 μm) at a high dilution, without being

affected by their density. Particle size distributions (PSD) and their averages may be obtained. The separation takes place in packed (PHDC) or in open tubular capillary columns. Components are eluted in the order of decreasing size, as in size exclusion chromatography (SEC), a method which has many features in common with HDC. HDC appears as a complement, either to SEC, which is limited to small size and solute species, or to other fractionation processes based on the effect of an external field, e.g. field flow fractionation (FFF). They are all transport methods, but differ in order of elution and domain of separation. Resolution is examined below. Other techniques for size measurements are static ones and can be used to check the validity of the results from HDC. It is necessary to combine different measurement processes, according to the conditions and purposes required: to obtain a relative or absolute value, with or without separation, affecting or not the state of the sample, and depending on the size and resolution required.

In HDC the key value for a given particle of diameter D_p is called the separation factor R_F . This is the ratio of the highest elution volume (V_m) to that measured for this particle (V_p):

$$R_F = V_m/V_p \quad [1]$$

This factor is greater than one, the inverse of the situation in thin-layer chromatography (TLC), where the solvent migration is more rapid than that of solute. By plotting the graph of known D_p versus R_F a calibration curve is obtained. This allows interpolation of the diameter of an unknown sample (Figure 1A). Another presentation is similar to that of SEC, log D_p versus V_p (Figure 1B) or D_p versus ($V_m - V_p$).

Other terms, detailed below, have the same meaning as in general liquid chromatography. Despite interest in this method, there are only a few papers (around 200) in the literature, as compared to separation by other chromatographic principles. Those that do exist are related to theoretical as well as practical aspects. General presentation may be found in papers by Barth, Hamielec and Tijssen. Currently, effective applications and use are increasing.

Origin

The first fundamental work was published by Small in 1974. The term hydrodynamic refers to the main driving force for separation. Under certain conditions, the nonturbulent flow in the column can be considered to be Poiseuille flow. Laminar flow occurring at a Reynolds number less than 2000 ($Re = 2R\bar{u}\rho/\mu$, where R = tube radius, \bar{u} = velocity, μ = viscosity and ρ = density of medium), leads to a parabolic velocity profile in which the highest velocity is the centre of the tube (Figure 2A). For geometric reasons larger particles are statistically located preferentially in the axis of the capillary, whereas smaller ones are close to the walls. This difference in flow velocity is one of the separation mechanisms. Electrostatic effects must also be taken into account (Figure 2B).

The term separation by flow was initially proposed. Liquid exclusion chromatography has been used with porous packing. HDPC refers to a combined permeation and hydrodynamic process on small pore particles and porous hydrodynamic chromatography is used in packing with large pores. For capillary chromatography in more restricted conditions, another term has been used: tubular pinch chromatog-

raphy. In slalom chromatography, the hydrodynamic effect in the interstices between particles leads to increasing elution volume with sample size.

A more frequently used alternative is hydrodynamic fractionation, since the process involved is not a classical chromatographic one of mass distribution equilibrium between two phases. In fact, there is only one phase, the mobile phase as an eluent, and only one field, the hydrodynamic one (Figure 2A). In FFF, a set of techniques for particle sizing, another external field is added. The intention is to modulate the intensity of the second field to inverse the elution order (e.g. in steric FFF). In HDC with packed columns, the nonporous stationary phase is theoretically inert. For porous packings, which allow the use of smaller capillaries, the SEC process operates simultaneously with HDC. Improvements on the original process are described in many papers and have been developed mainly at Lehigh University by Silebi and co-workers.

Advantages and Limitations

The main advantages of HDC are that it is a rapid and convenient method for the separation of particles. It allows one to obtain a fingerprint of the size distribution with an easy-to-operate instrument, similar to those used in liquid chromatography, at room temperature. Direct analysis of the original colloid medium and the use of high dilutions avoid modification of a sample which may be observed in a dry state (e.g. shrinking under the beam in transmission electron microscopy), and any effect of interactions.

Existence of a unique, universal calibration curve allows calculation of D_p and PSD for any sample, since there is no effect of sample nature, surface charge and density on elution volume. At low ionic strength, no effect has been found of the chemical nature of the sample for vinyl copolymer colloids, even for those of low glass transition temperature, T_g . On the other hand, at high ionic strength, sample chemistry may present an additional parameter for separation. With this technique, there are none of the limitations encountered in liquid chromatography (solvent nature, stability and availability of stationary phase and temperature range).

However, there are some difficulties related to the proper choice of operating variables. Elution has been shown to depend on size and porosity of packing beads, eluent flow rate, ionic strength, pH and additives such as surfactants. It is evident that column length and diameter play a role on plate numbers, resolution and domain of measurement. Particle size may affect the total recovery of material (with packed columns). Moreover, it may act on the detector response. In consequence, the PSD might be affected by the incomplete recovery of particles, due to adsorption effects, mainly for larger particles. For example, total recovery is observed up to 200 nm only with 20 μm packing.

Intrinsic limitations include a low plate number, N , and low resolution, R_s , so that generally the number of peaks (peak capacity p) in a chromatogram is low (about 5–10). Quantitative interpretation for determination of particle size distribution needs calibration in order to establish correspondence between

sample size and elution volume and the relationship between signal intensity and amount of particles. Moreover, band broadening, common to every chromatographic process, has a larger influence on PSD because of the low resolution. The interpretation of data assumes that particles are spherical, although an equivalence has been found for elongated structures (1 μm particles appear as spheres of 0.153 μm diameter). Finally, soft materials may be deformed under the high rate of shear in packed column and orientation in flow may affect the apparent size.

Applications

There is no limitation to the nature of the sample, but most studies are in the polymer field. In control and in research, particle characterization is a necessity and numerous chemical and physical data have to be determined, such as molecular weight distribution (MWD) and averages (\bar{M}) or PSD. These values are key parameters for determining rheological, mechanical, thermal and optical properties, storage stability, film-forming capability and the general behaviour of polymer materials. MWD and \bar{M} are commonly measured by SEC and particle size may be obtained by a variety of methods.

To reduce use of organic solvents in the production of polymers (by bulk and in organic solvent processes), free radical suspension and emulsion polymerization heterogeneous processes are used. The first process leads to larger bead sizes (around μm), which are not dealt with in HDC but HDC is typically suited for latex evaluation (around 100 nm) obtained by the second process. These polymer particles are used either largely in water-borne paints, inks and relatively low cost coatings, or as high value colloids for model compounds. For instance, they are used as standards for calibration (membranes) or in biochemistry for diagnostic aids and purification, or for packing chromatography columns. Much of the practical HDC work has been devoted to synthetic organic colloid separation and diameter measurements for quality control. Separation of natural products such as proteins is also of interest. The rapidity of the measurement is compatible with kinetic studies and monitoring during the polymerization process. Swelling of carboxylic latexes has been measured according to pH. The stability of mini-emulsions (50–500 nm) has been studied successfully. Flocculation of colloids in the presence of water-soluble ionic polymers or inorganic oxides has been observed by HDC in conjunction with other methods. Association of particulates under the effect of a thickener is clearly demonstrated, though it can be broken by intensive shear, and the same applies to aggregates.

Some authors have attempted to determine molecular weight or size for very large polymers, for instance water-soluble ones, like polyacrylamide, xanthane, polysaccharides and tobacco mosaic virus. The flow and dynamic behaviour of macromolecules in packed bed have been studied.

A variety of other compounds have been examined, such as carbon black, paper fibres, cement, clay, metals and oxides of Fe, Ti, Si, Al, silver halides and biomaterials such as milk or liposomes from egg yolk lecithin. Silica has been extensively used since it has the advantage of being a hard spherical model for HDC mechanism studies.

Moreover, HDC is of interest in the fundamental study of flow behaviour in tubing or pores which are encountered in transport technology of materials. Applications are also found in geology.

Equipment

Instrument

The instrument is similar to a liquid chromatograph: solvent source, pump, injection valve and column. Optical detection is spectrometry, refractometry, turbidimetry or light scattering.

Conditions to be satisfied are accurate flow rate control and high detection sensitivity. The first condition is due to the narrow elution domain and the second to the small injected volume of a very dilute sample.

Optical detection is more difficult since particle dimensions are in the range of the wavelength involved, λ . With a UV spectrometer, sensitivity is so high that as few as 25 particles in the detector cell give a noticeable signal. Sensitivity varies with wavelength, sample type and with sample size since the signal depends on absorption and scattering, which vary with sample diameter to the power a . The result is that quantitative interpretation needs preliminary signal calibration for each species.

A general formula in liquid chromatography for the instantaneous detector response H at each elution volume V is:

$$H = \sum N_i(V) D_i^a(V) K_i(V) \quad [2]$$

where K_i is the extinction coefficient for particles of diameter D_i and $a = 2$ in the Mie scattering regime for a turbidity detector. In the Rayleigh regime, valid for $\lambda/D_p < 0.3$, $a = 6$ for turbidity and 3 for refractometry. Hamielec observed a factor 6 in turbidimetry and a linear increase of signal with particle size in refractometry: there was a three times increase between 100 and 500 nm for polystyrene (PS) collo-

ids. For the same given weight of PS colloids, the UV signal is three times higher for 354 nm than for 88 nm particles. This also explains the effect of wavelength on signal shape and intensity. The peak separation is better with a refractometer, which may appear less sensitive than the turbidity detector. Generally, $\lambda = 254$ nm is chosen, but differences in relative sensitivity at $\lambda = 380, 254$ and 220 nm for PS colloids of 38 nm and 176 nm diameter have been found; this variation for larger PS colloids, 0.84 μm and 4 μm diameter, was also observed. A continuous and moderate increase in specific extinction coefficient at 254 nm and a higher and nonmonotonous increase at 220 nm have been measured. A low signal obtained for small particles may be enhanced by working at lower wavelength so that the apparent separation is increased. Difference in absorption may allow the apparent separation of PS/PVC. Intermediate values of a may correspond to a combination of a and $K(V)$. The value $a = 1$ holds for refractometry and spectrophotometry of polymers in SEC, so that the range 1–6 must be considered for a general data treatment.

Assuming the formulas for number and weight average diameters:

$$\overline{D}_n = \sum ND / \sum N \quad [3]$$

$$\overline{D}_w = \sum ND^4 / \sum ND^3 \quad [4]$$

and the simplified general relationship H proportional to ND^n , (K and a are independent of V), then:

$$\overline{D}_n = \sum (H/D^{n-1}) / \sum (H/D^n) \quad [5]$$

and:

$$\overline{D}_w = \sum (H/D^{n-4}) / \sum (H/D^{n-3}) \quad [6]$$

For all the investigated PS latexes, average diameters of the number and weight greatly decrease when n is increased (Figure 3). The best agreement with values measured with transmission electron microscopy is obtained for $n = 3$ –4, which is in agreement with theory since their diameters are in the range of the wavelength of detection (254 nm). Except for $n = 2$, the polydispersity index $P = \overline{D}_w / \overline{D}_n$ is not affected by n , and is the same for all samples. Nevertheless, these distributions do not correspond to true ones. The high polydispersity values compared to those determined by transmission electron microscopy (1.02) clearly show the necessity of a band-broadening correction.

A number of workers have built apparatus for HDC by putting together high performance liquid

Figure 3 Effect of n value on average diameters: number (circles) and weight (squares) for standard PS latex 106 nm. (Reproduced with permission from Revillon A and Guillard JF (1990) Software for data acquisition and treatment: hydrodynamic chromatography (HDC) analysis. *Journal of Applied Polymer Science: Applied Polymer Symposium* 45: 125–137.

chromatography components. Matec Applied Scientific (Hopkington, MA, USA) currently markets a high resolution instrument CHDF-1100 with UV detection. Separation is operated in a narrow capillary (2.5 $\mu\text{m} \times 10$ m) enclosed in a cartridge. Careful choice of eluent components avoids blocking the column for long-term use. Control of temperature allows accurate flow rate. The signal resulting from absorption and scattering is treated with the help of Mie theory. A mixture of small size latexes is well separated in about 10 min. Length of column may be increased, and diameter may be changed to cover different particle sizes. The apparatus may be used in process control.

Improvements to enhance the accuracy of R_F and PSD, resolution, sensitivity of detection and rapidity of analysis include the following:

1. The injection valve may be replaced by a 12-port valve and a delay column, with two injection loops (Valco Europe, Vici, Switzerland). This allows the injection of two (identical or different) samples on one or two consecutive columns. One of the advantages is the accurate determination of R_F by the help of an internal standard, avoiding sample mixing or reaction, and peak interference. Moreover, the comparison of the signals of the sample passing through active and inert columns allows determination of percentage particle recovery.
2. An additional fine metering valve (Vernier Handle, 18/21Y, Hoke, Creskill, NJ, USA) may be placed before the packed column to divide the main flow into two parts, one entering directly

into the column and the other through the injection valve. This reduces peak asymmetry from 5 to 1.5 and increases plate number by a factor of two. The optimum effect is obtained when the flow is divided in two equal parts; the main flow is less diluted and the side flow entering the column, close to the injection point, prevents broadening of the liquid jet containing the sample.

3. Effort has been put into the reduction of void volume, by direct column injection, design of a detector with reduced connection and cell volumes, on-column detection, improved sensitivity and the use of micro-equipment similar to that used in liquid chromatography and SEC.
4. Recycling, as used in SEC, may improve resolution or R_F determination without changing or increasing the R_F value.
5. A diode array UV-visible spectrometer allows simultaneous determination of the signal at several wavelengths, which means either signal enhancement or decrease (masking of a component).
6. Laser light scattering is of high sensitivity and may also be used, combining photon correlation spectroscopy with integration of the signal, at one angle, during a low counting time (a few seconds). It may give directly both the instantaneous size and concentration of the sample. Low angle laser light scattering is the detector used to determine the molecular weight of polyacrylamide. Variants of this include the evaporative light-scattering detection and condensation nucleation light-scattering detection. To overcome a calibration problem and use of standards, online viscosity has been proposed as an alternative, but this method awaits the development of improved pressure transducers. Fluorometry has been suggested as a high sensitivity detector for tagged polymers. The approach in the author's laboratory is discontinuous measurements of sample size on eluted fractions by transmission electron microscopy, photo correlation spectroscopy and sedimentometry.

Dispersion Correction

Even with micro-equipment and enhanced resolution, selectivity generally appears low. Results must be corrected for band spreading, in order to get individual peaks and true distribution.

There are many approaches for solving the dispersion problem based on Tung's equation, which expresses the experimental chromatogram, $F(v)$, as the result of the true chromatogram, $W(y)$, times a dispersion function, $G(v - y)$:

$$F(v) = W(y) * G(v - y) \quad [7]$$

This equation has received integral and numerical solutions. It has been shown that skewed instrumental spreading functions derived from the plug flow dispersion model fit data for particle separations by HDC, where the spreading function is:

$$G(v, y) = \{4(\pi Pe^{-1}(v/y))\}^{-0.5} \times \exp\{- (v - y)^2/4Pe^{-1}(v/y)\} \quad [8]$$

(where the dispersion term or Peclet number, $Pe = UL/D'$ when U = superficial velocity, L = length of the packed bed, D' = empiric dispersion coefficient; v = elution volume and at the maximum of peak = y). Increasing Pe leads to narrower peaks.

$Pe = 100$ corresponds to no peak correction. With packed column, whatever the value of n , \overline{D}_n increases with Pe , the effect is stronger for higher exponent, n . On the other hand, \overline{D}_w increases or decreases with Pe , depending on n . A quasi-constant value corresponds to $n = 3-4$ (Figure 4).

In another representation of results for different Pe values, \overline{D}_w versus n curves for all samples have a common intercept between $n = 3$ and 4. A rapid change of D is noted up to $Pe = 500$, then \overline{D}_n and \overline{D}_w tend to converge slowly, independently of n .

Practically, considering the whole set of results with UV detection, n must be chosen as 3-4 and Pe 500, to get the best average and distribution values, as well as narrow peaks, which means enhanced resolution.

Experimental Parameters

Sample is put in the liquid used as the eluent; the eluent which must be filtered (e.g. 0.22 μ m: Millipore) to prevent contamination and ensure long-term reproducibility. No other specific treatment is needed. Weight concentration is in the range of 10^{-4} , depending on the detector. This concentration does not need to be known exactly. A small amount of this solution or suspension is transferred with a syringe into the loop of a six-port valve. Loop capacity is typically from 1 to 50 μ L. Samples are injected separately or in mixtures. It is necessary to ensure high accuracy in data acquisition, since the useful elution domain is narrow. Frequent flow rate calibration is also necessary, with the ability to correct small changes in elution volume. With most detectors, the signal increases linearly with concentration or injected volume, in a range useful for application. This means, that no interaction, adsorption or overloading occurs. Peak characteristics are not affected.

Figure 4 Effect of n and P_e values on average diameters: number and weight for standard PS latex 234 nm. (Reproduced with permission from Revillon A and Guillard JF (1990) Software for data acquisition and treatment: hydrodynamic chromatography (HDC) analysis. *Journal of Applied Polymer Science: Applied Polymer Symposium* 45: 125–137.

For packed columns, the usual eluent is deionized water with additives, such as traces of formaldehyde to prevent bacterial contamination. A variety of ionic (e.g. sodium lauryl sulfate, about 1 g L^{-1}) and nonionic (AOT/Rohm & Haas, Brij, Triton/American Cyanamid) surfactants may be used at a concentration of $1\text{--}10 \text{ mmol L}^{-1}$. Ionic strength is preferentially ensured by sodium nitrate (0.5 mmol L^{-1}). A buffer may be added. Organic solvents may have interesting thermodynamic features and have been used for some applications.

Column dimensions are $0.8\text{--}1.1 \text{ m}$ in length and even $15\text{--}50 \text{ cm}$, with inner diameter from 2 to 10 mm . Sometimes two shorter columns, which are easier to pack, are assembled in series. Glass may be the column material, but stainless steel is more common. Column packing diameter has decreased from $20\text{--}100$ to $5\text{--}10 \mu\text{m}$, so that the number of plates is about $30\,000$ for a 0.5 m column. $N = 42\,000$ is obtained with small particles of $1.4 \mu\text{m}$ and 15 cm length. Flow rate varies from 0.07 to 0.7 mL min^{-1} , but is generally about 1.5 mL min^{-1} .

With capillary columns, aqueous and organic eluents have been tested with various additives in the aqueous eluents similar to those described above. Organic eluents may be advantageous because of their physical properties (viscosity, refractive index, solvating power) but the preferred eluent is water. Flow rate varies from 0.1 to 3 and even 9 mL min^{-1} , but is generally about 1 mL min^{-1} .

The reference sample, used as marker for determination of maximum elution volume V_m , is generally $\text{Cr}_2\text{O}_7\text{K}_2$ or $\text{Cr}_2\text{O}_7\text{Na}_2$, giving a high intensity signal. Compounds such as salicylic acid with the fluorometer or tritiated water may also be used.

Reference materials for calibration are monodisperse PS latexes, prepared by emulsion polymerization in the laboratory or commercially available. Quantitative measurements on peaks are: height (H), base width (w), half-height width ($w_{1/2}$), skewing or asymmetry factor ($sk = a/b$, ratio of second to first part of the peak width at $h/10$), absolute (V_e) and relative (R_F) elution volumes.

Liquid Carrier

The effect of additives in water (surfactant, ionic strength and viscosifying agents) will be considered here.

Surfactant Colloids must be stabilized sterically and/or electrostatically. The surfactants are either bonded or adsorbed on the particles; in the latter case, a part passes in the dispersing phase when dilution takes place (for injection and during the elution) so that flocculation can occur. Moreover, experiments with packed columns have shown that surfactants play a role in elution. Silebi observed a decrease of R_F when concentration is increased, but no change in the slope of $\log D$ versus ΔV . This is shown in Figure 5, for R_F at various amounts of sodium dodecyl sulfate (mmol L^{-1}) in the presence of $0.2 \text{ mmol L}^{-1} \text{ NaCl}$.

Sodium dodecyl sulfate is frequently used below or above its critical micellar concentration (2.5 g L^{-1}). This agent provides wettability of beads and ensures a low ionic strength (0.01). This favours higher R_F , better elution and increased resolution. The effect is greater for larger particle sizes. Other work has found that nonionic surfactants lead to higher R_F than

Figure 5 Effect of surfactant (SDS) on R_F , in the presence of NaCl 0.2 mmol L^{-1} . Open circles, 0.13 mmol L^{-1} ; open squares, 0.26 mmol L^{-1} ; open triangles, 0.52 mmol L^{-1} ; filled circles, 1.08 mmol L^{-1} . (Adapted with permission from results of Silebi CA and MacHugh J (1978) In: Becher P and Yudenfreund MN (eds) *Emulsions, Lattices and Dispersions*, pp. 155–173. New York: Dekker.

ionic ones, whereas stabilization by anionic surfactants is claimed to be considerably more effective than with nonionic ones. It is important to bear in mind that molecules of surfactant are in equilibrium with micelles above the critical micellar concentration. Depending on the amount and nature of surfactant in the sample, a new equilibrium between sample and eluent may explain the differences in observed results. It has been reported that SDS, tested from 0 to 4.8 g L^{-1} improves baseline, peak shape and reproducibility and increases R_F in capillary columns.

Ionic strength Electrolytes may have four effects:

1. on the limiting R_F value
2. on percentage recovery
3. on the size domain of interest
4. on sample chemical composition

Electrolytes greatly modify the critical micellar concentration of the surfactant and affect the repulsive electrostatic double layer around the particles. Basically, a low ionic strength I is necessary for screening charges. Recall that:

$$I = 0.5 \sum c_i Z_i^2 \quad [9]$$

where c_i = total concentration of species i , of valency Z_i .

1. Increasing the ionic strength, I , leads to a decrease in R_F (Figure 6). In the initial work, even the ionic marker was affected: a 3% change in V_m was observed when increasing NaCl concentrations by a factor of 1000. Initial results obtained with packed columns have been confirmed by several

Figure 6 Effect of ionic strength I (Na_2HPO_4) on R_F for three PS latexes of diameter 100 nm (triangles), 200 nm (squares) and 300 nm (circles) in the presence of 2.67 mmol L^{-1} surfactant. (Adapted with permission from results of Silebi CA and Mac Hugh J (1978) In: Becher P and Yudenfreund MN (eds) *Emulsions, Lattices and Dispersions*, pp. 155–173. New York: Dekker.

authors, who observed a change in R_F with ionic strength I , due to competition mainly between van der Waals (attractive) and double-layer (repulsive) forces. At high ionic strength, elution is opposite to the normal mode. The reason could be that very strong van der Waals interactions dominate over the hydrodynamic effect. Some authors have observed a normal decrease in R_F when I increased, but no change in the slope of $\log D_p$ versus ΔV .

2. Percentage recovery is decreased for various colloids when I is increased on a $20 \mu\text{m}$ packing but is more constant for PS on large pore, large packings (63 – $125 \mu\text{m}$ Fractosil). A short column favours the recovery of large particles.
3. Change of I may make possible the separation or the elution of large particles (limit 850 nm instead of 500 nm), even if N or R_F is decreased.
4. In addition, the chemical composition of the sample can affect the elution, so that a mixture of polystyrene and poly(methylmethacrylate) (PMMA) latexes of identical size (240 nm) can be separated in the presence of 0.4 mol L^{-1} NaCl , on a 1 m column packed with $20 \mu\text{m}$ PS beads. On the other hand, there is no elution difference between latexes of PS and PMMA of diameters from 58 to 207 nm , when NaCl is varied from 4.44 to 15.6 mmol L^{-1} .

In capillary columns, no effect was observed for either NaNO_3 (0 – 28.6 g L^{-1}) or NaCl (0 – 48.7 g L^{-1}). Peak shape and elution volume of samples and marker were not modified – or only slightly – by variation in the salt concentration, but NaNO_3 has some absorption and affects the baseline.

Viscosity additives Some authors have observed a change in R_F mainly for larger particles, in the presence of ethylene glycol or sucrose. A small amount of ethylene glycol prevents aggregation. Theoretically, transverse motion must be decreased with decreased tailing and increase in R_F , when the viscosity is increased. In this respect, polymers have been used with some success. Neither increase in R_F nor shape improvement in peaks was observed in the range 0–6% ethylene glycol with capillary columns. The pressure is markedly increased, according to Darcy's law and a permeability coefficient, K_o , may be derived. For $L = 60$ m, a K_o value of $2.4 \times 10^{-8} \text{ m}^2$ is far lower than that of filtration membranes (10^{-12} m^2), which indicates the low separating power of a capillary column.

As a result of these observations, only the surfactant SDS at 3 g L^{-1} was used as an additive in capillary columns.

Flow rate, Q and nature of the eluent Flow rate may have two effects: one on N and one on the sample.

A high flow rate may induce polymer deformation or degradation. It was found that under 2.5 cm s^{-1} no deformation of soft polymer is expected from a calculation using a Deborah number.

Increase of resolution by a factor of 2 has been observed with a 10 times decrease of flow rate, but the effect is small if the packing is of very small particle size. It is known that, in general, low flow rates favour minimum equivalent plate height, H_e , according to the van Deemter equation:

$$H_e = L/N = a + b/v + cv \quad [10]$$

where v is linear velocity. Here, this general expression holds with zero as c value, since it represents the mass transfer term. In capillary HDC diffusion has been found to be $b = 7 \text{ cm}^4 \text{ min}^{-1}$ and $a = 10 \text{ cm}$ for longitudinal and eddy terms, respectively. These values, which are far higher than in liquid chromatography, mean a high sinuosity coefficient and large equivalent bead sizes.

In capillary columns, N , R_S and R_F vary differently with eluent (water) flow rate Q , depending on sample size. Number of plates was found to increase with flow rate, but R_F decreases for a $4 \mu\text{m}$ sample and the resolution is slightly affected. Some deformation of peaks was observed at low flow rates. For instance, the resolution between $0.84 \mu\text{m}$ particles and marker or $4 \mu\text{m}$ particles was unchanged, but was decreased between $4 \mu\text{m}$ and marker. The interpretation may be found in the tubular pinch effect, by taking account of the respective Reynolds numbers of the particles, Re_p (see above).

Their values correspond to very different flow rates so that a change in mechanism occurs in the investigated region.

These different results for R_S , N and R_F show that operating conditions are not rigid and they must be chosen as a function of the particular analysis. Depending on the objective, it may be required to obtain either rapid results in 1.5 min with medium resolution or higher resolution in 36 min. It is also interesting to note that the highest number of plates is obtained not only for the marker, but for the largest sample.

In methanol, the number of plates increased from a constant value for 0.84 and $4 \mu\text{m}$ particles and marker to a maximum for the $10 \mu\text{m}$ sample, when Q increased. The resolution, like R_F , decreased when flow rate, Q , was increased.

Tetrahydrofuran has low viscosity and is a good solvent for polymers. These characteristics may allow higher flow rates and the study of polymers in solution. In fact, although excellent baselines, very high number of plates and good chromatograms of cross-linked PS ($10 \mu\text{m}$) were obtained, the upper limit of R_F was decreased with this solvent. In tetrahydrofuran polybutadiene, polyisoprene and PS of nearly the same molecular weight ($300\,000$) were eluted according to their respective dimensions, $r_g = 28.9$, 26.6 and 25 nm on a packed column.

Water, being a more versatile eluent, and offering a good compromise between R_F and N values, is the main solvent at a flow rate of about 1 mL min^{-1} with a capillary column. This flow rate also corresponds to a compromise between higher R_F (Figure 1A) and lower resolution at the higher velocities. Table 1 summarizes the experimental conditions and results.

As an ancillary practical application, Poiseuille's law allows the determination of one of the parameters: flow rate Q , pressure P , length L , viscosity μ and capillary radius R :

$$\Delta P = 8\mu LQ/\pi R^4 \quad [11]$$

Table 1 Experimental conditions with capillary columns

Length (m)	30	60	120	120	60	120
Radius (μm)	125	125	125	125	250	125
Eluent	W	W	W	Meth	W	THF
Maximum R_F	1.4	1.45	1.45	1.45	1.6	1.26
N (m)	500	900	1900	7000	400 ^a	5300
Maximum N (m)	16.7	15	15.8	58.3	38.3	250

Columns

Capillary columns for capillary HDC are used for larger particles, generally in the range from 1 to 60 μm . New capillary columns allow separation in the sub-micron range. Packed columns are effective for smaller particles, with diameters of 30–1000 nm. Since its introduction, HDC studies have been mainly devoted to separations with packed columns.

Packed columns Columns may be slurry- or dry-packed in the same way as for liquid or gas chromatography. Packings used include ion exchange resins, cross-linked poly(styrene-divinylbenzene), nonporous glass and silica gel among others. As an example, analysis has been performed with a slurry-packed column (cross-linked PS spheres of uniform diameter 20 μm ; 50 cm length, 0.78 cm internal diameter).

The main determining parameter is packing particle size. A general trend in liquid chromatography is an increase in plate number when particle diameter decreases (N is inversely proportional to the square of particle diameter). It has been shown in the initial work on HDC that resolution is increased by using packings of small monodisperse spheres; **Figure 7** shows this result. Moreover, resolution is also decreased when size increases (more than a factor of 2 between 20 and 40 μm). Whatever the size of the packing material, the elution region is very limited, defined by a maximum ratio R_F of 1.15 in most papers. By using 2 μm nonporous silica gel packing and tetrahydrofuran as eluent, a value of 1.21 is obtained for R_F , yet the chromatogram contains only five peaks: four for PS and one for toluene. R_F values as high as 1.3 have been obtained.

Figure 7 R_F versus packing diameter for five latexes. Open circles, 1000 nm; open squares, 800 nm; open triangles, 600 nm; filled circles, 400 nm; filled squares, 200 nm. (Adapted with permission from results of Small H (1974) *Journal of Colloid and Interface Science* 48: 147–161.

Large (125–180 μm) but porous particles are still used (at low flow rate: 2 cm min^{-1} , in the presence of 0.01 mmol L^{-1} NaCl) to take advantage of the pores as capillaries, with an R_F value of 1.16 or up to 1.39 in the measurement range 240–1230 nm. The equivalent capillary radius R is 2.8 μm , calculated according to the formula:

$$R = \frac{r_p}{1 - \sqrt{2 - R_F}} \quad [12]$$

By combining HDC and SEC, and using porous particles, the R_F may be increased by a factor 1.1–1.2 to a value of 2 or 2.2. The peak broadening decreases or increases, so that resolution is inferior to that obtained on nonporous packing. Moreover, small size porous packings in SEC (2 μm Hypersil or polymeric 3 μm packing with 5 or 15 nm pore radius) allows a high plate number in a 0.45 cm column to be obtained, with an expected peak number of 66. Considering a resolution of unity, constant with V , the peak capacity is:

$$p = 1 + (R_F - 1)N^{0.5}/4R_F \quad [13]$$

This leads to $p = 37$ in this case, and the number obtained is approximately 15, which is an excellent value. The authors of this work also used nonporous monodisperse particles, leading to the theoretical plate height minimum value (5 μm), with no dependence of flow rate in the range 3–7.5 cm min^{-1} . N is 42 000 for a 15 cm length column, with 1.4–2.7 μm silica particles so that a mixture of styrene polymers in the range of molecular weight 10^4 – 10^7 are well separated in 6 min, but shear degradation occurs for the higher molecular weight polymers.

Capillary columns With open capillary tubular columns, the resolution is poorer than with packed columns, but the R_F may be as high as 1.45, so that the peak capacity may be the same as that obtained with a packed column.

The main parameters are length and diameter. A systematic study of the length has been made with stainless-steel columns of 30, 60 and 120 m, and internal diameters of 0.25 and 0.5 mm. The 30 m column gave results of insufficient quality, so most of the work was done with the 60 m columns and finally optimized with 120 m length columns. By going from 60 to 120 m, the theoretical plate height was found to be unchanged and N increased from 380 to 800, for a 4 μm sample. A way to illustrate this increase in resolution is to consider the calibration as represented in SEC. A lesser slope (Figure 1B) allows a better separation.

Table 2 Characteristics of capillary hydrodynamic chromatography systems

Length (m)	Internal diameter (mm)	N (m)	Maximum R_F max
88–201	250–500	?	1.3
50	180–450	25	1.5
60–200	250–500	10	1.55
15	100	25–200	> 1.2
0.45–7	1000	6	1.5
0.15–0.2	1	250	1.1
0.7–3.3	1.2–10	105	1.05
91–168	250–500	16–100	1.4
12	15 000	?	1.15
30–120	250–500	16–250	1.5
2	4	2000	> 1.15
2	6.5	?	1.42
5	7	600	1.63
2.5	10	580	> 1.46

The second characteristic of the column is its diameter. Table 2 summarizes conditions of separation and typical results (N , R_F). It can be seen that capillary diameter varies considerably, from 1 to 1000 (or even 15 000) μm . Most of the initial work has been done with 250–500 μm internal diameter column. The choice of tube diameter corresponds to the different ranges of sizes to be separated. The limit in R_F shows that over a certain sample size, no separation occurs. This limit of size may be related to the ratio of the average radius of the sample, r_p , to the tube radius, R . A third order law, relating r_p to R , may have a reasonable approximation in a linear one in agreement with Small's observations:

$$r_p = f + kR \text{ (}\mu\text{m)} \quad [14]$$

with $f = -7$ and $k = 0.1$ (R and r_p in μm). A column of diameter 500 μm may have a medium range of separation of 18 μm instead of 5 μm for the 250 μm one. Taking into account the published results, the ratio of R to r_p is about 100, and for a given diameter of column, the usable r_p/R range varies roughly from 10^{-3} to 10^{-1} . The interest in large diameter columns

is because of the decrease of rate of shear, γ , but the resolution is higher for narrow tubes.

To reduce extra-column band broadening, optimization of the injection-detection system has been attained with 50–100 μm capillaries judging by results obtained in capillary electrophoresis. With microcolumns, efficient separation has been obtained for PS samples with molecular weight of 10^3 – 10^6 Da. The chromatogram was similar to that of SEC, but with a limited R_F of 1.1 (instead of 2 in SEC) and a low number of plates ($N = 50$). Work by Tijssen shows a very high number of plates ($N = 10^5 \text{ m}^{-1}$), but a more limited R_F , of 1.05. The increase in N was not accompanied by an increase in R_F , so that the peak capacity remained low (less than 10). More recent work indicates higher values of R_F : 1.63 and rather good resolution between latex samples. Even with 4000 plates, the peak capacity is only about 7. Table 3 summarizes the conditions and results observed with capillary and packed column HDC.

Mechanism and Other Methods

Some of the difficulties for M or PSD determination may be solved using other types of chromatography: liquid, FFF – normal and steric (SFFF) – supercritical fluid, capillary electrophoresis, or combining with other methods (thermal FFF). Countercurrent chromatography or centrifugal partition chromatography is a potential tool for separating copolymers of different structure or nature, but currently there are few examples. These methods correspond to a large variety of separation mechanisms based on kinetics or thermodynamics, where surface, volume, active specific sites of materials and thermal, gravity, electric, magnetic applied fields bring their contribution. They are also called fractionation and have features in common with chromatography. One characteristic is the absence of the stationary phase, which avoids the problems of interfering phenomena such as adsorption, mass transport, column channelling, degradation and shear rate. This allows a greater choice of eluent.

Some other solutions are nonchromatographic methods, working with or without separation, such

Table 3 Comparison between capillary and packed columns for HDC

Column Type	Length (m)	Diameter (mm)	V (mL)	u (cm s ⁻¹)	Shear (s ⁻¹)	ΔP (bar)	N	N (m)	H (cm)	R_F max	Range (mm)
Capillary	120	0.25	5.9	34	10^{-4}	175	1500	12.5	8	1.45	0.8–20
packed	0.5	5	7.4	0.1	10^{-8}	35	7000	14 000	0.007	1.15	0.05–1

as dynamic light scattering (photocorrelation spectroscopy) and sedimentometry under centrifugation in a disc. In the presence of SDS, at low ionic strength, HDC results in the range of 200 nm are slightly higher but close to disc centrifuge values. The latter method is of high resolution, since the separation time is inversely proportional to the diameter squared. Analysis time is low in photocorrelation spectroscopy (1 min) and is similar for HDC and centrifugation in a disc. Photocorrelation spectroscopy operated with a proper choice of parameters, gives an excellent correlation with transmission electron microscopy values and an excellent resolution for the mixture of two latexes.

Mechanism of Separation Mode

Classical chromatographic separation occurs because of the differences in partition of compounds between mobile and stationary phases. More generally, separation is the result of local differences in distribution of the sample compounds in the mobile phase. The partition coefficient K is related to the thermodynamic relationship: $\ln K = \Delta G^\circ/RT$, which indicates the possible effects of three factors: enthalpy (ΔH) or entropy (ΔS) changes, and temperature T (Kelvin). Practically, separation is achieved under the effect of two forces (or fields) operating in one or two phases. One phase is necessary for transport and may have a physical or chemical role in the separation.

In HDC, separation results under the effect of one hydrodynamic field which is moving one mobile phase. The nature of the mobile phase is theoretically irrelevant, but differences in results obtained with different solvents have been observed. The separation is due to the existence of a flow-velocity profile in the channel, in which small particles tend to be closer to the external wall, where the flow is stagnant. If a packing is present, its only role is to decrease the capillary size. Voids between beads (diameter Φ_p) in packed columns play the role of small channels of continuously variable diameter similar to a set of capillaries. Bird proposed the equation:

$$R = \Phi_p \varepsilon / 3(1 - \varepsilon) \quad [15]$$

where ε is the ratio of interstitial volume to total column volume, i.e. about 0.35–0.40, so that R is around $\Phi_p/5$ –6. In consequence, the mechanism of HDC in packed or capillary columns may be described by the same parallel capillary model.

The velocity profile $u(r)$ is parabolic, obeying Poiseuille's equation:

$$u(r) = dP(R^2 - r^2)/4\mu dL \quad [16]$$

where dP and dL are increments of pressure and column length, R is the column radius, r is the particle radius and μ is the eluent viscosity. It is easy to see that $u(0)$ is a maximum when $u(R)$ is zero. The average fluid velocity, \bar{u} , is:

$$\bar{u} = \frac{\int_0^R u(r)r dr}{\int_0^R r dr} = \frac{R^2 dP}{8\mu dL} \quad [17]$$

which is half that of the maximum. A particle in the fluid is assumed to have the same velocity as the flow, in its gravity centre, and moving from the column to a distance $R - r$ of the wall:

$$\bar{u}_p = \frac{\int_0^{R-r} u(r)r dr}{\int_0^{R-r} r dr} = \bar{u} \left\{ 1 + \frac{2r_p}{R} - \left(\frac{r_p}{R} \right)^2 \right\} \quad [18]$$

Taking into account the definition of R_F , we derive:

$$R_F = \frac{\bar{u}_p}{\bar{u}} = 1 + 2\left(\frac{r_p}{R}\right) - \left(\frac{r_p}{R}\right)^2 \quad [19]$$

An additional term expresses the rotational motion, so that the velocity profile is:

$$\frac{\bar{u}_p}{\bar{u}} = 1 + 2\left(\frac{r_p}{R}\right) - \gamma\left(\frac{r_p}{R}\right)^2 \quad [20]$$

where γ is a wall effect parameter, the value of which depends upon the radial position of the particle (from about 1 to 60). In capillary HDC R_F must be independent of length L , but the coefficients of the equation are quite far from the theoretical values. This expresses the fact that R_F is higher than expected and that particles move far from the wall.

For small r_p/R (about 0.1), R_F is a linear function of r_p/R . In fact, the corresponding curve tends rapidly to a plateau value. This means that this equation is valid for one particle and is only the result of the hydrodynamic effect. If allowance is made for non-zero stagnant volume, another term is required to complete the above equation. It includes the fraction K of stagnant volume available for polymer and V_s and V_m , stagnant and mobile volumes, respectively:

$$u_p = \Delta P \{ (R^2 - (R - r_p)^2 - \gamma(r_p^2)) / \{ 8\mu L(1 + KV_s/V_m) \} \} \quad [21]$$

The concentration profile of particles, $C_p(r)$, resulting from Brownian diffusion and colloidal interactions, must also be taken into account:

$$\bar{u}_p = \frac{\int_0^{R-r} u_p(r) C_p(r) 2\pi r dr}{\int_0^{R-r} C_p(r) 2\pi r dr} \quad [22]$$

where:

$$C_p(r) = A \exp(-\phi(r)/K_B T) \quad [23]$$

after a sufficient diffusion in the column. K_B is the Boltzmann constant and $\phi(r)$ an energy term depending on packing and particle interactions. ϕ is the resulting sum of repulsive double-layer and attractive van der Waals forces (Born repulsive forces are of negligible effect). A graphical representation of the overall profile of particle concentration is shown in Figure 2B. Van der Waals forces depend on the Hamaker constant and double-layer forces depend on latex surface potential and dielectric constant of particles and packing. The result is:

$$\bar{u}_p = \frac{\int_0^{R-r} u_p(r) \exp\left(-\frac{\phi(r)}{K_B T}\right) r dr}{\int_0^{R-r} \exp\left(-\frac{\phi(r)}{K_B T}\right) r dr} \quad [24]$$

The exponential term may be corrected by another one accounting for the particle migration under inertial hydrodynamic force and electrokinetic lift effects. Many experiments have been carried out to fit elution (volume and peak width) results and equations, by adjusting these values. Listing of the results is more relevant to colloid chemistry than HDC.

Another effect must be considered, described as early as 1836 when Poiseuille observed a corpuscle-free region near the wall in blood vessels. More precisely, Taylor observed an uneven distribution of erythrocytes in flowing blood: there was low concentration not only near to the wall but also near to the centre, provided the velocity was large enough. Further studies concluded that radial forces tend to carry a rigid sphere to an equilibrium position at approximately $0.6R$, depending on the velocity and on the ratio r/R . This was called the tubular pinch effect. Experiments were done with large spheres (0.16–0.85 mm radius in a tube of radius 5.6 mm, at a velocity from 5 to 90 cm s⁻¹ and viscosity from 17 to 410 cP. Ploehn assumed that lateral migration of small particles is primarily due to diffusion, while large particles are focused by the inertial force at an equilibrium position, as observed in the tubular pinch experiment. This experiment may be responsible for separation in the capillary column (see above).

Resolution

We now turn to comparison of resolution (R_s) in the different fractionation processes: we shall examine R_s value and its variation with elution volume.

Table 4 Resolution of various fractionation methods

Parameter	Capillary HDC	HDC	DCP	TFFF	SFFF	SFC
R_s	0.15	0.15	1.5	0.7–2	2.2	1.2
R_t	0.025	0.025	0.15	0.2–0.02	0.07	0.03
t (min)	6	6	10	45–120	30	20–60
ϕ (μm)	> 1	< 1	< 60	< 1	< 2	0.05

Reprinted with permission from Revillon A (1994) *Journal of Liquid Chromatography* 17: 2991–3023. CHDC, Capillary HDC; DCP, centrifugation under disc; TFFF, Thermal FFF; SFFF, steric FFF; SFC, supercritical fluid chromatography.

Firstly, we define a specific resolution (R_{sp}) = R_s /ratio of the diameter of the species under consideration. Secondly, we define resolution per unit time (R_t) = R_{sp} /time of measurement, in order to compare different samples and different elution conditions, respectively. To obtain polymer dimensions in solution, molecular mass, M , is converted to diameter, applying the equation: diameter is proportional to $M^{0.6}$.

R_s depends on chemical or physical factors, packing size being one of them. As a general rule in chromatography, resolution increases when the particle size of the packing decreases. In HDC with packed columns, the R_F ratio is increased by using fine packings and resolution is increased. Pore size and pore volume, being the origin of molecular separation in SEC, strongly affect elution, whereas the effect of porosity is controversial in HDC, where the main phenomenon takes place essentially between – and not in the porous part of – the packing particles. Combined HDC and SEC action increases separation, in terms of sample mass and elution volume (see above).

For SEC, HDC, supercritical fluid chromatography and TFFF, theoretical plate height generally increases with flow rate according to the van Demter equation, so that resolution decreases. Sometimes R_t may increase, particularly if a gradient is used properly or when mass transfer does not play a role.

For all separations, it is possible to obtain an accurate molecular weight by using deconvolution to remove system dispersion.

Table 4 indicates meaningful values of R , R_s , R_t and analysis time with the various separation systems.

Conclusion

HDC is a complementary method for particle characterization in the micron size range. It is rapid, low cost, easy to carry out and very sensitive. It allows separation and size measurement of organic colloids,

soft and rigid polymers and various materials (spheric or elongated) in about 10 min, without special sample preparation. Moreover, it has been the subject of many theoretical studies, assuming different mechanism models and explaining the effect of parameters on separation. Effort has been directed to column design, detection sensitivity and fit of chromatogram for PSD. Some conditions must be obeyed to obtain reliable results, whatever columns are used. Firstly, there is the need for accurate calibration, with frequent adjustment of parameters and choice of a column set giving a low slope. Secondly, there is the need to adjust the detector response factor (exponent n of diameter) to the sample and to the chosen detector. Thirdly, axial dispersion must be corrected using a simple equation. As a consequence of the combined analysis of the effects of n and Pe , the proposed value for exponent n was 3.5 with UV detection and a Peclet number of 500. Results have been compared on eluted fractions with those of direct methods. With proper use of HDC interpretation parameters, PSD and average diameters are in agreement with those obtained by other methods, for instance photon correlation spectroscopy and sedimentometry, this last technique has high resolution as its main characteristic.

In packed columns, packing size, ionic strength, I , nature and amount of surfactant have very large effects on R_F and other elution parameters, such as percentage recovery, which decreases for large particles. R_F decreases when I or packing size or amount of surfactant increases. Porous packings may add a SEC separation effect, enhancing R_F . Improvements in packing material (5 μ m) and methodology tend to use a 0.5 m long column.

In capillary HDC, the effect of additives is low; surfactants are the most useful. The separation factor R_F is fairly constant in water but is strongly affected by flow rate in methanol. The high number of plates in tetrahydrofuran is not accompanied by a high maximum R_F value. This separation factor may be higher with a 60 m than with a 120 m column, but the resolution, R_S , is not so high. This emphasizes the fact that R_F , R_S and N may vary independently.

Micro-equipment (diameter of the capillary in the micron range, short column (10 m), on-column injection and detection) enhances resolution and R_F as it lowers axial dispersion. Peak capacity remains limited at about 10, but for rheological properties and size range, this is an interesting alternative to packed columns.

Introduction

On-line coupling of high performance liquid chromatography (HPLC) to capillary gas chromatography (GC) means that LC fractions comprising one or several peaks are directly transferred to the gas chromatograph, mostly in a fully automated mode.

The first coupled system, developed by R. Majors in 1980, involved splitless injection by means of a GC autosampler and merely transferred a small part of an LC peak. The first transfer of complete LC fractions was described in 1984. Full transfer is essential, first because of sensitivity (the sample capacity of LC is limited), and second, to obtain reliable quantitative results. The main obstacle to overcome was the introduction of 100–1000 μL volumes of LC eluent into a gas chromatograph.

LC-GC seldom corresponds to ordinary LC with GC added as a detector. Usually GC performs the main analysis and LC is specially designed for a kind of pre-separation or clean-up. The technique presupposes that the compounds to be analysed are amenable to GC, i.e. that they are of limited polarity and rather low molecular mass. For most applications, only normal-phase LC is suitable, either because the matrix material to be injected is not soluble in reversed-phase eluents (e.g. mineral or edible oils), the components are derivatized prior to LC, or the sample consists of an extract from an aqueous phase.

LC columns are kept small (mostly of 2 mm i.d.) in order to keep the fraction volumes below 1000 μL . For the isolation of wider fractions of compounds, solid-phase extraction-type cartridges of lower separation efficiency, yielding smaller fractions, may be more suitable.

In contrast to clean-up by solid-phase extraction (SPE) cartridges, HPLC columns are used over long periods of time. During GC analysis, they are reconditioned, commonly by backflush with a stronger solvent.

Purposes of Coupling LC to GC

Clean-Up

Much of LC-GC serves for the routine analysis of a single or a small group of trace components, i.e. for automated clean-up at high separation efficiency. The LC detector installed between the LC and the GC enables careful optimization of the LC pre-separation and accurate cuts of the window transferred to the GC. Optional 'peak detection' automatically compensates for shifts in LC retention times by the use of the up- and/or down-slope of a peak determined by the LC detector.

Often LC-GC is used for the elimination of time-consuming manual sample preparation. In other instances, only the separation efficiency of HPLC is adequate for the removal of disturbing material of similar characteristics. The determination of traces of ergosterol or $\Delta^8(14)$ -stigmastenol in edible oils, fats, or food extracts in the presence of far larger amounts of phytosterols are examples. A number of applications even involve two-dimensional LC with heart cutting or LC-GC with intermediate solvent evaporation.

Group-Type Separation

Characterization of complex mixtures often necessitates prior separation into classes of compounds. Examples are the LC fractionation of mineral oil and its products into aliphatics and aromatics of a given number of aromatic rings, the analysis of the pattern of the alkylidibenzothiophenes in mineral oil, the determination of sterol dehydration products for the detection of adulterated olive oils, or the determination of irradiation in fatty foods through olefins cleaved from the triacylglycerols.

Sample Enrichment

Large amounts of some samples can be injected into the LC under conditions that remove the matrix and enrich the components of interest. At least 10 mL of water can be injected, reconcentrating the organic material on, for example, a reversed-phase C_{18} column. Salts are removed and the organic material fractionated by a suitable mobile phase before transfer to the GC.

Transfer of LC Fractions

On-line transfer must be capable of introducing many hundreds of microlitres of LC eluent into the GC. While this has been routine for almost a decade for normal-phase LC eluents (typically based on pentane or hexane), transfer of water-containing eluents is still at an experimental stage, both as a result of technical difficulties, and because of limited applicability.

Routine transfer in on-line LC-GC is mostly achieved by on-column techniques. Usually an early vapour exit is used, releasing the solvent vapours through an outlet installed after a pre-column system. This protects the GC detector and accelerates the discharge of the large volume of vapours (increases the evaporation rate). An uncoated and/or a retaining pre-column is used. The uncoated pre-column serves to evaporate the eluent and reconcentrate the initial bands of higher boiling solutes by the retention gap effect. The coated pre-column retains the solutes during release of the solvent.

Distinction must be made between fully and partially concurrent solvent evaporation. Fully concurrent evaporation means that all the eluent is evaporated during introduction into the GC, i.e. no liquid accumulates in the pre-column system. Volumes of up to several millilitres can be transferred, but volatile components are lost. Partially concurrent evaporation leaves behind unevaporated solvent that must be retained by a relatively long uncoated pre-column and vaporized after the end of the transfer. It is used when solvent trapping is needed for the retention of the volatile components during release of the solvent vapours; components as volatile as heptane can be analysed quantitatively in pentane.

The most obvious alternative to on-column transfer, programmed temperature vaporizing (PTV) solvent splitting, has been proposed, but not described as a routine technique so far.

On-Column Interface

The on-column interface is used for the transfer by partially concurrent evaporation (see Figure 1).

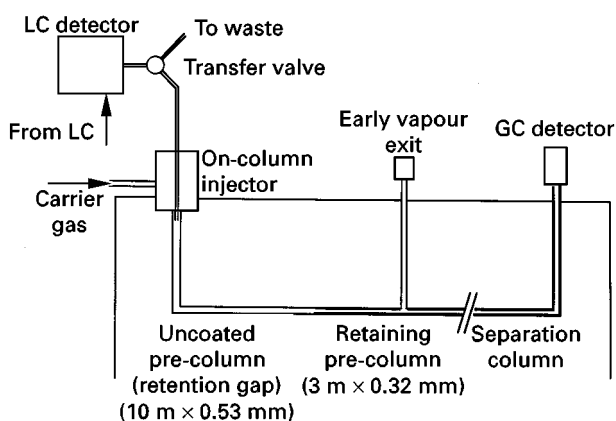

Figure 1 On-column interface for samples containing highly volatile solutes.

Transfer occurs by the same principles as on-column injection of large volumes (retention gap technique). The eluent from the LC passes through a valve for selecting the fraction to be introduced into the GC. It then enters an uncoated pre-column of typically 10 m \times 0.53 mm i.d., with a capacity of retaining 100–250 μ L of wetting liquid. Partially concurrent evaporation ensures that LC fractions with larger volumes do not overfill the uncoated pre-column. Mostly a retaining pre-column (2–3 m \times 0.32 mm i.d.) has been used, but if the early vapour exit is closed before the end of solvent evaporation, it is not really needed. The technique has been routinely used for fractions of up to 800 μ L volume.

Loop-Type Interface

Transfer through the loop-type interface (Figure 2) is used for fully concurrent evaporation and is suitable for the analysis of components eluted at oven temperatures above about 150°C. It is the technique most frequently used because of its simplicity: the introduction rate is self-adjusting and the end of the transfer

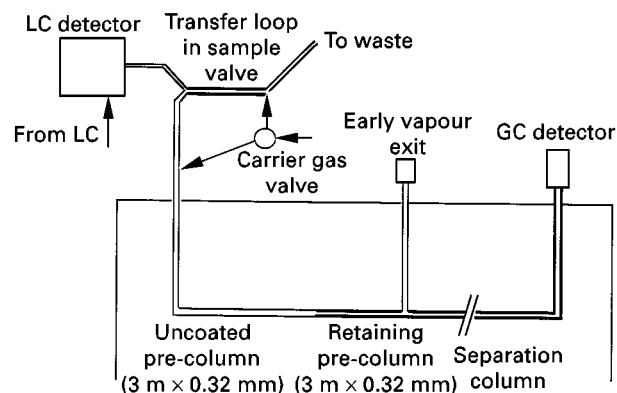

Figure 2 Loop-type interface for transfer by concurrent eluent evaporation.

can be detected automatically. The maximum volume transferred to date is 20 mL.

The LC eluent passes through a loop mounted in the sample valve with an internal volume chosen to match the volume of the LC window to be transferred. At the end of the fraction, as observed by the LC detector, the valve is switched and the carrier gas pushes the liquid from the loop into the GC pre-column. The temperature of the GC oven is above the solvent boiling point at the carrier gas pressure, which causes the liquid to be stopped as soon as it enters the oven-thermostatted pre-column. The vapours are discharged through the coated pre-column retaining the solutes, driven by the pressure of the carrier gas behind the plug of liquid to be transferred (overflow technique). A separate valve actuated simultaneously with the sample valve feeds the carrier gas either behind the liquid to be transferred or to a T-piece allowing purging of the sample valve during analysis.

Stop-Flow Introduction

In 1985, Cortes described LC-GC by a 'stop-flow' transfer technique. The interface used is shown in Figure 3. A valve either conducts the LC eluent to waste and supplies the carrier gas to the GC column, or transfers the LC fraction to the GC while the carrier gas flow is interrupted. The vapours are discharged by expansion during evaporation, driven by their own vapour pressure (also called 'overflow').

Vaporizer/Overflow Interface

The vaporizer/overflow interface (Figure 4) is a further development of the stop-flow technique. The transfer valve sends the LC eluent either to waste or into a vaporizer chamber typically thermostatted at around 300°C, replacing the uncoated pre-column. Actuated simultaneously, a separate valve (to avoid contact with solvent) stops the carrier gas supply during transfer. The vaporizer consists of 0.32 mm

Figure 3 Stop-flow interface.

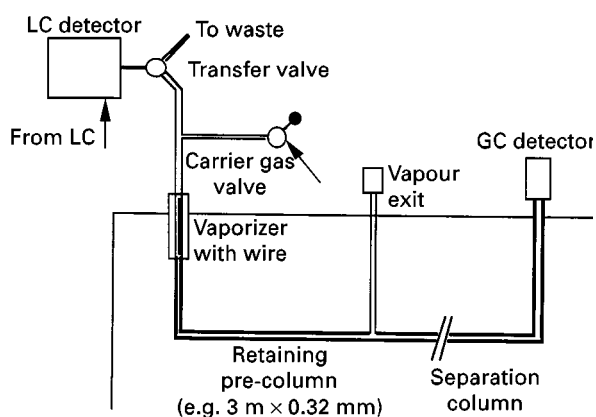

Figure 4 Vaporizer/overflow interface.

i.d. fused silica capillary with a piece of wire (bare metal or metal deactivated by the Silcosteel™ procedure) inserted to prevent liquid from shooting through the chamber. The oven temperature is selected to be near the minimum that avoids solvent recondensation, i.e. at, or slightly above, the boiling point at the pressure required to discharge the vapours (usually 5–15°C above the standard boiling point). A retaining pre-column (typically 2 m × 0.53 mm i.d.) connects to the T-piece of the vapour outlet. Compared with the loop-type interface, the technique improves the retention of the volatile solutes. However, no solvent trapping can be achieved.

Vaporizing Chamber Interface

For the transfer of water-containing eluents or LC fractions containing amounts of nonevaporating material disturbing on-column introduction, a vaporizing chamber is inserted between the on-column injector and the pre-column system (Figure 5). It consists of a packed liner of 1–2 mm i.d. and is thermostatted at a high temperature (around 300°C) in order to supply the large amount of heat consumed by solvent evaporation. Vapours are discharged by a carrier gas stream through the vapour exit. An uncoated pre-column is used for partial solvent recondensation if solvent trapping is required, but is of no utility for nonwetting water-containing eluents.

Applications

It is estimated that currently about 200 automated on-line LC-GC instruments are in use. More than half of the applications are in three fields. These were determined by the people involved rather than by particular suitability of the technique and should, therefore, not be understood as an indication that other applications would not be at least equally promising.

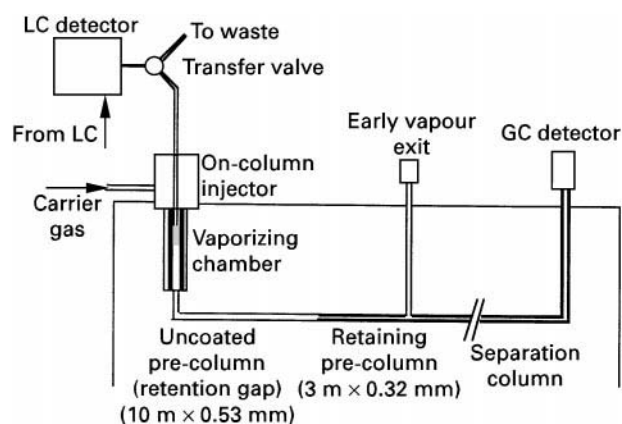

Figure 5 On-column interface with vaporizing chamber.

Mineral Oil Analysis

The petroleum industry has used LC-GC for the pre-separation of products into paraffins and aromatics, as well as for the separation of the highly

alkylated aromatics into classes of given ring number (using an amino column). Bartle used the same technique for analysing exhausts from diesel engines. Mineral oil products and their aromatic components have also been determined in foods.

Edible oil

Methods have been developed for the analysis of edible oils or fatty foods in order to achieve faster analysis (circumventing manual clean-up) and analyses of trace components that are difficult to analyse otherwise. They include the analysis of sterols (after transesterification of the oil), the minor components in the oil (after silylation), sterol dehydration products, volatile terpenes in cold-pressed oils, contamination by mineral oil or polyaromatic hydrocarbons, and organophosphorus insecticides.

Figure 6 demonstrates the extremely high resolution achievable by on-line LC-LC-GC-FID for the

Figure 6 Liquid chromatogram and LC-LC-GC-FID chromatograms of the fractions marked: analysis of sterol dehydration products of rapeseed oil. (Reproduced with permission from Grob K, Biedermann M and Mariani C (1994) LC, GC and GC-MS of sterol dehydration products. *Riv. Ital. Sostanze Grasse* 71: 533-538.

analysis of sterol dehydration products from refined rapeseed oil (the composition of which is of interest for detecting adulteration of other oils, e.g. olive oil). Sample preparation consisted of preparing a 1:5 dilution of the oil. The first LC column isolated the hydrocarbons (with the column backflushed by a stronger eluent after each analysis), while the second one separated the products of interest into groups, such that the closely related compounds could be separated by GC. The fractions from LC-LC and the related gas chromatograms are numbered.

Water Analysis

Brinkman, Vreuls, Noij and others have worked on the enrichment of organic materials from water on LC cartridges, followed by on-line liquid or thermal desorption into a gas chromatograph. The aim is a permanent, fully automated analysis of pesticides and other critical contaminants in rivers or the supply lines of water works. A standard procedure consists in extraction of 1–10 mL of water on short polymer-packed LC columns, which are then washed with clean water and dried by a stream of nitrogen. After desorption with ethyl acetate, the sample is transferred through the on-column or loop-type interface.

Conclusion

On-line LC-GC techniques are extremely powerful with regard to selectivity, sensitivity (as a result of the excellent clean-up) and efficiency (as most manual sample preparation is integrated into the automated analysis). It seems, however, that currently they are too demanding for widespread routine use.

Paper Chromatography

I. D. Wilson, AstraZeneca Pharmaceuticals, Mereside, Alderley Park, Macclesfield, Cheshire, UK

Copyright © 2000 Academic Press

Introduction

The techniques of paper chromatography and paper electrophoresis are sufficiently intertwined as to be worth considering together, as indeed they often were in books and reviews at the height of their popularity.

Paper Chromatography

The origins of paper chromatography have been traced back by some authorities as far as Pliny (23–79 AD), who described the use of papyrus impregnated with an extract of gall nuts to detect ferrous sulfate. Further examples of the use of paper chromatography can be seen in the 19th-century work of the German chemist Runge who described in his book *Zur Farbenchemie* the use of this type of separation for the investigation of inorganic mixtures. Subsequently another book (*Der Bildungstrieb der Stoffe*) by

Runge appeared, containing examples of this work. Further work in this area was undertaken by Schonbein and his student Goepplshroeder, who investigated the technique of *Kapillaranalyse* (capillary analysis). However, these early studies seem to have stimulated little real interest and, although there appear to have been some limited further studies in the 1930s and 1940s, it was not until the seminal work of Consden, Gordon and Martin in 1944 on the analysis of amino acids in protein hydrolysates, and subsequent studies by Consden, Gordon, Martin and Synge, that paper chromatography made a major contribution to separations.

Paper chromatography is now obsolete, except perhaps as an inexpensive technique for teaching chromatography in schools and colleges. However the introduction of paper chromatography may truly be regarded as revolutionary, and was one of the innovations in partition chromatography that led ultimately to the award of the Nobel prize to Martin and Synge in 1952. One author stated, in a handbook on the topic, that 'By this stroke of genius, they changed the analysis of protein composition from a lifetimes' work to a 2–3-day simple technique that could be carried out in any laboratory'. So rapid was the adoption of the technique that a book on the subject published in 1954 contained nearly 4000 references to its use. Quotations from textbooks of the period contain statements such as 'Paper chromatography is so widely used that it is impossible to make more than a rough estimate of its application' or 'it can be stated that there is virtually no field of chemistry or biology in which paper chromatography has not made a substantial contribution to the furtherance of knowledge and understanding'.

However, despite its huge impact at the time, paper chromatography suffered from a range of problems that led to its rapid replacement by thin-layer chromatography (TLC), to which it was inferior in almost every respect. In particular, separations on paper were often very slow (often up to 10 or 20 h), and spots tended to be much more diffuse than, for example, separations on cellulose TLC plates.

The Practice of Paper Chromatography

Equipment

Probably the major advantage of paper chromatography, and one that ensured its rapid adoption, is the simplicity of the equipment required in order to perform it. Essentially this equipment is the same as that now used for TLC and all that is required is a suitable

type of paper to act as the stationary phase, a means of applying the sample, a developing tank and a solvent system. A typical set-up for descending paper chromatography is illustrated in **Figure 1** showing, in addition to the tank and solvent reservoir the anti-siphon rod used to prevent excessive solvent flow from flooding the paper. Tanks were normally operated with the atmosphere saturated with the vapours of the solvent used for development in order to ensure good and reproducible results.

Solvents

In general, the solvent systems used in paper chromatography were based on mixtures of one or more organic solvents with water. Acids (HCl, acetic, etc.) or bases (aqueous ammonia) were added to control the ionization of the analytes. Typical solvent mixtures for amino acids, for example, might be composed of butan-1-ol, acetic acid and water; butan-1-ol, pyridine and water or phenol and water. For sugars, solvents based on ethyl acetate, pyridine and water; ethyl acetate, propan-1-ol and water or ethyl acetate, acetic acid and water were popular. For inorganic ions, solvent systems such as acetone, concentrated HCl and water; pyridine and water or butan-1-ol and HCl mixtures were suitable. In the case of some of these solvents the mixtures suggested separated on standing into two phases. In such circumstances it was customary to separate the two phases and use the aqueous layer to saturate the atmosphere in the developing tank and the organic layer as the eluent for chromatography.

Papers

The media used for both paper chromatography and paper electrophoresis were based on filter paper, with Whatman no. 1 being perhaps the most widely used and no. 3 also popular. However, paper manufactured by other companies was also used and Schleicher & Schull 2043b paper was popular according to some sources. Paper suitable for use in paper chromatography was also manufactured by Munktell, Macherey Nagel, Eaton-Dikeman and D'Arches. Not surprisingly, the availability of a range of papers produced numerous studies comparing the relative merits of the different products, eliciting the somewhat jaundiced comment in one review of the subject that 'These workers are not always in agreement ... and it is probable that the differences introduced by their individual experimental methods are of a greater magnitude than the differences between the various grades of paper'. Some papers were available in slow, standard and fast grades with the speed of development controlled by the coarseness of the cellulose fibres and the packing

Figure 1 A typical commercial system (Shandon Unikit) for descending chromatography. (A) Set-up for hanging the paper, which hangs freely over the anti-siphon rod (1) and dips into the solvent reservoir where it is held in place with the anchor rod (2). (B) The assembled reservoir and paper in place in the developing tank. At this point the solvent would be added and the tank closed with the lid.

density. In general, the standard papers gave the best compromise between speed and resolution, with fast papers more suitable for simple separations and the slow papers used where the greatest resolution was required. Whilst suitable for analytical work, these papers were often replaced in preparative applications by more specialized materials such as Whatman no. 3 MM and 31ET or Schleicher & Schull 2071. In addition to pure cellulose, a variety of modified papers were also produced, including ion exchange materials, acetylated or benzoylated papers, silicone oil-impregnated papers, as well as silica and alumina-impregnated papers.

Modes of Paper Chromatography

In most of its practical aspects (e.g. sample application, equipment such as developing tanks and visualization procedures), paper chromatography somewhat resembles TLC. The most noticeable difference is that, as the paper is not rigid, it must either be suspended from an appropriate support during development or arranged in such a way as to be self-supporting. Only the major types of paper chromatography are described below, but it should be noted that there were many minor variants of the technique (e.g. centrifugal, continuous).

Figure 2 (A) One method of ascending chromatography involved the formation of a self-supporting cylinder, held together with tongued clips. The cylinder was then placed in a tank containing the solvent for development (B).

Ascending Paper Chromatography.

In the ascending mode of development the paper is suspended so that the lower edge is below the level of the solvent, and the solvent moves up via capillary action. An alternative to suspending the paper was to form a self-supporting cylinder from the paper. These arrangements are illustrated in Figure 2. As with TLC, multiple development, with either the same or different solvent, was used to improve resolution, although the time taken for each development must have made this especially tedious to perform.

Descending Paper Chromatography

The descending method of chromatogram development was that originally proposed by Martin and his co-workers. In descending paper chromatography the upper end of the paper is immersed in a solvent contained in a suspended trough so that the flow, initiated as in the ascending mode by capillary action, is sustained by gravity and will continue so long as there is solvent to feed it. This had the useful consequence that a sheet of any (practical) length could be used. In addition, the solvent could be allowed to run off the end of the paper, thus extending the chromatographic run if needed to improve resolution, or enabling compounds to be eluted from the paper

and collected for further experiments. The results obtained for a particular sample/solvent system combination run in either ascending or descending mode were usually similar; however, the latter was generally faster.

Two-dimensional Separations on Paper

Where separations were not achieved in a single development, it was often possible to achieve the desired result using a second solvent system of different composition and development in a second dimension at 90° to the original direction of chromatography. Two-dimensional paper chromatography was first described by Consden, Gordon and Martin for the separation of 20 amino acids, but was subsequently widely employed. An additional possibility was the use of paper chromatography in one direction with paper electrophoresis (both high and low voltage) in the second. Indeed, there are numerous examples in the literature of either chromatography followed by electrophoresis or electrophoresis followed by chromatography. A typical example of the type of result that could be obtained using two-dimensional paper chromatography is shown in Figure 3, whilst Figure 4 shows the combination of electrophoresis followed by chromatography in the second dimension for amino acids in fruit juice.

Figure 3 A two-dimensional separation of a mixture of black and brown ink using butan-1-ol-ethanol-2 mol L⁻¹ aqueous ammonia (6 : 2 : 2) for the first development and butan-1-ol-acetic acid-water (6 : 1.5 : 2.5) for the second dimension, on Whatman no. 1 paper. Key: 0, origin; 1, dark blue material remaining at or near the origin; 2, yellow pigment; 3, pink pigment; 4, diffuse brown pigment; 5, pink pigment; 6, yellow pigment; 7, scarlet pigment; 8, pink pigment; 9 and 10, faint spots of orange and yellow pigments respectively.

Horizontal or Circular Paper Chromatography

Horizontal (or circular) paper chromatography was performed in two ways. In the classical method, a spot of the sample to be analysed was placed at the centre of a circular filter paper. Then a short wick was made by making parallel incisions *c.* 2 mm apart from the edge of the filter paper to its centre. This wick was then cut to an appropriate size and bent so that it dipped into the solvent contained in a Petri dish. The general arrangement is shown in Figure 5A. Sub-

sequently, apparatus became available that eliminated the need for cutting the paper to form a wick, and one such is shown in Figure 5B.

Preparative Paper Chromatography

For a time preparative paper chromatography was an important method for the isolation of substances, leading to comments such as: 'These methods are so well developed today that some laboratories prefer them to the methods of column chromatography'. The simplest methods of preparative paper chromatography were essentially scaled-up versions of the analytical methodology using either several sheets of paper or custom-made preparative cardboards (e.g. Schleicher & Schull 2071). In addition, techniques were developed such as the Chromatopile (a number of discs of filter paper in a tightly compressed stack to form a column, with development by either ascending or descending chromatography), the Chromatopack (strips or sheets of paper pressed together to form a block which was then developed as if it were a single sheet) or rolls of filter paper wound over a core of polyethylene and inserted into a polyethylene column (sometimes these rolls were placed in a pressurized jacket). Using such techniques the preparation of milligram quantities of material was readily achieved.

Figure 4 A typical two-dimensional separation of amino acids in orange juice effected by electrophoresis in pyridine-acetic acid followed by chromatography with butan-1-ol-acetic acid-water for the second. Detection with ninhydrin.

Figure 5 (A) Horizontal circular paper chromatography based on the method devised by Rutter. The upper part of this diagram shows 1, the paper; 2, the circle of sample applied to the paper (this could also be in the form of individual spots of different samples); and 3, the wick cut into the filter paper. The paper was supported on a Petri dish (4) containing the solvent (5) into which the wick was dipped in order to initiate development. Later the methodology was adapted by the introduction of a special development chamber which removed the need to cut a wick into the paper. One such, based on the apparatus devised by Kawerau, is shown in (B): 1, lid; 2, paper; 3, solvent capillary; 4, adjustable collar; 5, solvent.

Applications of Paper Chromatography

Given the importance of paper chromatography in its heyday, a list of its applications covers all types of analytes, including proteins, peptides, amino acids, poly-, oligo-, di- and monosaccharides, natural products, sterols, steroids, bile acids, pigment, dyes and inorganic species. A typical application to the separation of a series of inks is shown in Figure 6.

Paper Electrophoresis

It is possible to trace the development of paper electrophoresis back to the work of König, beginning in 1937 with a publication in Portuguese. However, this work attracted little interest at the time and it was the

Figure 6 Separation, by ascending paper chromatography, of a series of ink samples (in duplicate). Key: RB, royal blue; Bk, black; G, green; Br, brown; Sc, scarlet; O, origin; SF, solvent front. Solvent system butan-1-ol-acetic acid-water (6:1.5:2.5) with Whatman no. 1 paper.

later work of Wieland and Fischer on amino acids in 1948 and Durram on serum proteins (1949, 1950) that attracted the attention of the scientific community. Some measure of the importance of the technique in its heyday may be gained from the observation in a volume on paper chromatography and electrophoresis published in 1957 that 'more than 2000 papers dealing with the subject of zone electrophoresis have appeared. Over 90% of these have dealt with paper electrophoresis'. Faced with such apparent success, it is possible to forgive the enthusiasm of the authors of a subsequent manual, published in 1977, on the subject who felt able to say that: 'In fact, it can be truly said that the history of paper electrophoresis still lies before it'. In fact, as with paper chromatography, this type of electrophoresis is now considered by most workers to be entirely obsolete.

The Practice of Paper Electrophoresis

Paper electrophoresis can be broadly divided into three main techniques: low voltage, high voltage and continuous. Of these, the low voltage (up to 1000 V) technique was probably the most widely used.

Low Voltage Paper Electrophoresis

Strips of paper arranged either vertically or horizontally and moistened with the buffer were used. The application of the voltage ($2\text{--}10\text{ V cm}^{-1}$) used to perform separations generated some heat, but this was generally carried away by evaporation when the open strip method was used. In the open strip technique the paper was suspended between the

electrodes in the saturated gaseous phase of the developing chamber. This suspension was accomplished in a wide variety of ways, with one review of the technique stating that: 'Paper has been arranged in this chamber in almost every conceivable configuration, but it is usually either pulled horizontally taut or allowed to hang free from a central support at the apex'. Both the horizontal and hanging strip methods were reported to provide excellent resolution, but the latter was claimed to give better reproducibility. Other configurations included the semi-closed strip, where the paper was supported on one side by a cooled glass surface to enable temperature control, and the closed-strip method where the paper was either held between two glass plates or submerged in a nonpolar immiscible liquid (e.g. heptane or carbon tetrachloride). With the former system, evaporation was not permitted and pressure could be applied so as to control the amount of electrolyte taken up by the paper. Using the nonpolar immiscible liquid method, some heat was removed from the paper by convection and conduction to a thermostatic bath. A simple commercial low voltage paper electrophoresis apparatus, of the open strip type, is illustrated in Figure 7.

As well as one-dimensional separations, two-dimensional paper electrophoresis was also performed when needed to improve particular separations.

High Voltage Paper Electrophoresis

The name high voltage electrophoresis was used to describe separations performed at voltages from 1 to 10 kV. The potential gradients used in high voltage systems were generally in the region of $50\text{--}100\text{ V cm}^{-1}$ and, as a consequence, one of the main problems encountered was heating. The apparatus used therefore required the presence of some form of heat exchanger to ensure that the heat was conducted away.

High voltage electrophoresis was considered to be best used for low molecular weight substances with many applications in amino acid analysis.

Continuous Electrophoresis

In continuous paper electrophoresis the sample was applied continuously to the paper (Figure 8), enabling a considerable volume to be applied over time, allowing preparative separations to be performed. The layout of the paper in this type of separation is shown in the diagram. Thus, the paper is suspended vertically (often referred to as a curtain) so that the buffer solution flowed downwards (as in descending chromatography). A field was then applied across the direction of the flow, causing the ionic substances to be separated, as indicated in the figure. The individual components of the mixture could be collected into appropriate receptacles as they eluted from the paper.

Figure 7 A simple commercial apparatus (Shandon Unikit) for paper electrophoresis. (A) The electrophoresis assembly showing the application of the samples to the paper which is suspended in a V shape via a glass rod. (B) Once prepared, the assembly is placed in the tank and the current switched on.

Figure 8 The arrangement for continuous electrophoresis. (A) Sample was applied continuously at this point and travelled down the paper under the influence of the flow of buffer. Current was applied at the point indicated by + and -, causing the components (e.g. B) to separate. They could then be collected into suitable receptacles as they eluted from the paper at C.

Applications of Paper Electrophoresis

As with paper chromatography, the applications of paper electrophoresis were legion and included amino acids, organic acids, natural products such as alkaloids, polysaccharides, nucleotides, proteins, peptides, pigments and inorganic species. The scope of the applications of paper electrophoresis is best appreciated by reference to the texts indicated in the section on Further Reading.

Detection and Quantification of Substances on Paper Chromatograms or Electropherograms

As in TLC, following separation the papers are removed from the developing chamber and dried. Coloured spots were visualized directly without difficulty, whilst those that fluoresce under UV irradiation were also detected relatively easily. In the case of colourless compounds, many of the visualization procedures, of varying degrees of specificity, currently used for this purpose in TLC were also used for detection after paper chromatographic separation, using either spraying or dipping. Although considered

primitive by comparison with modern methods, separations on paper were also used for quantitative assays in addition to qualitative work. As with other planar methods, varying degrees of sophistication were employed, from comparison of the size of spots compared to a standard, cutting out the bands/spots and eluting the analytes for subsequent spectroscopic determination (i.e. UV, visible or fluorescence measurements) all the way up to the use of densitometry (with accuracies of $\pm 5\%$).

Conclusions

Paper chromatography and electrophoresis were once techniques of considerable importance but this is no longer the case. Whilst still useful as an aid to teaching chromatography in schools and colleges, there are virtually no situations where separations originally developed for paper chromatographic methods cannot now be performed faster and better by TLC. The same comments apply to the relationship between paper electrophoresis and the modern slab gel technique.

Introduction

Proteins are the essence of life processes. DNA contains the coded information for life, and is analogous to computer software, but it is the proteins that are analogous to the hardware, that actually carry out the job. Proteins have many roles, from catalysts (enzymes), through proteins that bind and interact with other molecules to control their behaviour, to structural and storage proteins which, although less functional, are nevertheless just as essential. Some proteins are 'solid', e.g. the proteins in our skin; others are soluble, such as those in our blood.

As with most separation procedures, those designed for proteins are designed to deal with a complex mixture of similar components, and separation often depends on slight and subtle differences between these components. Moreover, whereas some proteins may comprise a substantial proportion of the starting mixture, others may make up only a tiny fraction. The situation is very much like mining for minerals: first, select a source that is particularly enriched in the component you want, then work on removing all those you do not want. However, protein purifiers have one advantage over miners: nobody has succeeded in finding the philosopher's stone to turn base metals into gold, but molecular biologists do have the equivalent – the ability to greatly enrich the starting material with the desired protein. Consequently when talking about protein purification today, it is necessary to include a discussion of techniques for production of the protein by recombinant procedures. We also refer to the overall separation processes as 'purification', since the object is usually to obtain a homogeneous preparation of one single protein type, a 'pure' protein (even if this aim is not always quite achieved).

Separation procedures depend on differences in properties between the components, and fortunately proteins do come in a wide range of shapes and sizes. The properties that are exploited are solubility, ionic charge, size and shape, surface features and natural biological interactions. With recombinant techniques it is possible to modify the protein's structure so as to greatly simplify its purification.

The Starting Material

As indicated previously, the starting material should be rich in the protein of interest. That is not always possible, of course; the proteins may only come from a particular source, such as blood, mosquito larvae or potatoes (to name just a few possible sources). But even then it is possible to use molecular biology techniques to amplify the amount in either the natural source, or in an unnatural one, provided the gene (DNA) that encodes the protein, is known. Techniques for isolating the gene are outside the scope of this article, as are the details of the methods used for production of the recombinant protein, but both are becoming increasingly easy, and are often the first consideration when wanting to purify a protein. If the gene route is feasible, it will nearly always be the best way. Take the example of blood. Handling of human blood is now tightly controlled because of the dangers of viruses and because of ethical concerns, so if a blood protein can be produced in a fermentor full of yeast, or even in a cow's udder, these problems are circumvented. It is also much easier to produce a few grams of bacteria than a few grams of mosquito larvae.

Apart from simplifying and standardizing the raw material, the other two advantages of recombinant protein production are that (1) the amount of the desired protein, i.e. as a percentage of the protein in the starting material, will nearly always be much higher than in the natural source, and (2) simple techniques for modifying the protein by genetic means can make it very easy to separate from all the other proteins.

In most cases the desired protein will be soluble in aqueous media. If not, there are both advantages and disadvantages: the advantages include the ability to remove all the water-soluble proteins by simple extraction, which is a major separation process in itself. But the disadvantages include the problems of deciding what to do next, and how to separate the many insoluble proteins from each other. The answer is to get them into solution, and often this involves detergents, or other agents that may actually disrupt the natural biological state of the proteins. The natural state is called 'native' protein, whereas the disrupted state is called 'denatured'. It is sometimes possible to 'renature' a protein from the denatured state, and this may be necessary when recombinant expression of otherwise soluble proteins results in an insoluble, denatured product (inclusion bodies).

Solubility

Separation by solubility characteristics is the oldest technique in protein purification. Changes that result in proteins becoming less soluble in aqueous media include addition of salts, miscible organic solvents and organic polymers, and adjustment of pH. The aim is to make some proteins less soluble than others by varying these conditions, so the proteins can be separated from each other by centrifugation. It is not possible to predict which proteins will be affected, so it is essential to have a method for detecting the protein that is to be isolated, so that its position is known after any separation procedure. Typical precipitants include ammonium sulfate as a salt, ethyl alcohol and acetone as miscible solvents, polyethylene glycol as an organic polymer, and pH adjustment with a weak acid to about pH 5, which coagulates complex proteins.

After centrifuging the precipitate, it can be redissolved in a buffer that lacks the precipitant. **Table 1** illustrates an idealized analysis of the results of an ammonium sulfate fractionation of an extract containing an enzyme. Before the next separation procedure, it may be necessary to remove excess precipitant by dialysis or gel filtration.

Ionic Charge

All proteins have charges on them as a result of amino acid side chains such as aspartate, glutamate, histidine, lysine and arginine. The net charge on a given protein depends on its exact composition, and on the pH. Consequently at a given pH different proteins will have different net charges, and a shift in pH will change this value for each protein, though for all them it will become more negative for a higher pH, and more positive for a lower pH.

Although it is possible to exploit the charge differences by electrophoretic techniques, this has rarely been fully successful in preparative (as opposed to analytical) separations of proteins. The main problems have been in the design of reliable and safe equipment; there are some useful systems, but usually they will only be used when all else has failed. Ionic charge separations are carried out by ion exchange chromatography, which has been the most successful and widely used method of protein separation since its introduction some 40 years ago. Anion exchange columns have positive charges that attract negatively charged proteins, and at neutral pH most native proteins are negatively charged. For the minority of positively charged (high isoelectric point) proteins, cation exchangers are used. Samples are applied in a buffer that has low salt content (low ionic

Table 1 Results of a typical ammonium sulfate fractionation procedure in purifying an enzyme. Percentages are given as a percentage of saturation with ammonium sulfate. Specific activity is in units of enzyme activity per milligram of protein. Although the degree of purification is not high (2.1-fold), it is useful to note that much of the nonprotein material stays in the supernatant, and the precipitated fraction containing the enzyme can be dissolved in a much smaller volume than the starting extract. Results are also given for a second trial, in which recovery of activity has been sacrificed for a higher degree of purification

<i>Fraction</i>	<i>Volume (mL)</i>	<i>Amount of protein (mg)</i>	<i>Amount of enzyme (units)</i>	<i>Specific activity</i>	<i>Purification (x-fold)</i>	<i>Recovery (%)</i>
Extract	500	6000	380	0.063	1	100
0–50%	20	750	20			
50–60%	45	2400	310	0.130	2.1	82
60–70%	35	1600	70			
70% supernatant	540	1000	0			
0–55%	40	1500	90			
55–60%	35	1300	220	0.169	2.7	53
60% supernatant	535	3100	70			

Figure 1 Example of protein separation using anion exchange chromatography. (A) A diagram of the basic principles of the equipment. The amount of protein emerging from the column is monitored by detecting the absorbance of light in the ultraviolet region (280 nm or 215 nm) due to proteins, and separate fractions are collected automatically. (B) The elution pattern. Some proteins did not bind to this adsorbent, being positively charged at this pH. The elution position of a specific protein is indicated by the shaded peak.

strength), and proteins of the opposite charge to the column are adsorbed. Proteins are generally eluted by increasing the ionic strength with gradual salt addition to the buffer, so that proteins of successive adsorbing strengths elute as the salt concentration goes up. This enables relatively high resolution of separate protein components, giving a high degree of purification. There are many commercial adsorbents and equipment to use them with. The type to be used will depend very much on the purpose; 'high performance' systems are expensive to operate and may not be suitable for commercial production of the protein, but most suited to research and development. Speed may be desirable, or may be of little concern; there are materials for all needs. An example of the separation of a fairly complex mixture of proteins on a 'moderate performance' adsorbent is shown in Figure 1.

Size and Shape

The sizes of protein molecules vary over a large range, but most have a molecular weight 20 000–200 000 Da (native protein). This translates to a size, assuming a perfect sphere, of roughly 3–8 nm in diameter. Many proteins are not spherical, however, so their longer dimensions will be greater than these figures. Separation by size is carried out by a process called gel filtration or size exclusion chromatography. The principle of gel filtration is shown in Figure 2. Beads that are porous, with pores of similar size to the proteins, are packed into a column. The largest proteins cannot penetrate the beads because the pores are too small, so they flow quickly around the outside of the beads, and emerge first.

They do not emerge until after a volume (the void volume, V_0) that is equivalent to the volume of liquid outside the beads has passed through the column. This volume is typically about 30% of the total column volume, V_t . The smallest proteins are able to penetrate the pores in the beads. While in the beads they are isolated from the flow of liquid (which cannot pass through the beads because of capillary forces), and so do not move down the column. However, they do spend some time outside the beads, and eventually, after a full column volume has passed through, they emerge from the column at V_t . The gel

Figure 2 Principles of gel filtration. A mixture of proteins is applied to the column. Only the smallest molecules can penetrate the beads, while the larger molecules pass round the outside of the beads. Intermediate-sized molecules can partially penetrate the beads. As the separation continues, the larger molecules run out ahead of the smaller ones.

Figure 3 (A) The elution pattern of a mixture of proteins from a gel filtration column. (B) Plot of the 'elution volume' against the logarithm of the molecular weight. All small molecules emerge at V_t , all very large molecules earlier at V_0 , and the values for intermediate-sized molecules fall on a straight line over about a 10-fold increase in molecular weight range. By comparing the results with the elution volumes of proteins of known molecular weight, the molecular weight of an unknown protein can be determined.

beads have a range of pore sizes, so that intermediate-sized proteins can spend some time inside the beads, but not as much as the smallest proteins. Consequently the emergence volume of each protein is related to size, as shown in Figure 3.

This is also the principle used to separate large molecules from small molecules in general, and is very useful for removing salts from protein solutions. In this case the beads have pores so small that even the smallest proteins cannot penetrate the beads, but salts can.

Gel filtration is a very gentle method; the proteins remain in solution at all times, and need not be exposed to any extremes of pH or salt concentrations. Resolution depends on the relative sizes of the proteins in the starting mixture. Gel filtration will commonly be used at a later stage of purification, when the quantities of sample have been reduced.

There are also membranes available which have pores of suitable size to separate proteins. A force, such as gas pressure, is used to push the liquid, plus smaller molecules through the membrane. The largest molecules are retained, and concentrated

behind the membrane. This has application in the relatively crude separation of large proteins from small ones.

Separation by size is the commonest technique in the analysis of proteins, and is described in a later section. Using slab gels, which have pore sizes similar to the beads described previously, proteins are forced by electrophoresis to separate according to their size, the larger ones having more difficulty in finding their way through the gel, and so moving more slowly. This method has been applied preparatively, but only on a relatively small scale and mainly with unfolded, denatured proteins. Normally, one wants to isolate the protein in its native state, as not all proteins can be re-folded *in vitro*.

Other Surface Features of Proteins

The charged amino acids in a protein are responsible for the properties that allow separation on the basis of overall electrical charge. Other amino acids, especially those exposed on the surface of the molecule, confer other properties that can be exploited in separation methods. In particular, hydrophobic side chains would prefer not to be in contact with water. These amino acid side chains like to stick to each other, or to some surface that is also hydrophobic, and will do so in preference to being surrounded by water.

An adsorbent that consists of fat-like molecules attached to the insoluble beads is called a hydrophobic adsorbent, and will attract those proteins that have a larger proportion of hydrophobic side chains on their surface. Hydrophobic interactions are strengthened by inclusion in the solution of high concentrations of certain salts such as sulfates. A typical procedure would be to add up to 1 M sodium sulfate to the protein mixture, then run it through a column of hydrophobic adsorbent. Many proteins will not bind; these have few hydrophobic side chains. Then the salt concentration is gradually decreased, and proteins successively elute. The most hydrophobic proteins remain even a low salt concentration, and need other solutes such as chaotropic salts (e.g. thiocyanates), nonionic detergents, or high concentrations of glycols to elute them.

The most widely used method that exploits hydrophobic interactions is generally known as high performance liquid chromatography (HPLC). In this application proteins are adsorbed onto a material containing an aliphatic chain, such as C8 or C18, in conditions that result in partial unfolding of the native state of the protein so that internal hydrophobic regions are exposed. An increasing gradient of organic solvent then weakens the interactions between the protein and the adsorbent. Each protein is eluted

Figure 4 Principles of affinity chromatography. A ligand W that the desired protein binds to naturally is immobilized by attachment to column material. The protein mixture is applied, and the desired protein sticks to the immobilized ligand, while other proteins pass through and are washed away. Ideally only the proteins that bind to ligand W are left, though in practice there are usually others. Consequently a second 'affinity' step, involving washing the column with the natural, free ligand, is used to displace the specific proteins from the column.

in a narrow and very reproducible range of solvent concentrations, and provided that the proteins refold rapidly as they are eluted, this gives a very high resolution of components. This has been highly successful with small proteins and peptides, but is less useful for larger and more unstable protein components.

Bioaffinity

One surface feature that most proteins have is a binding site that corresponds to their natural physiological role. Enzymes, for example, bind to substrates known as ligands, which may be small molecules or parts of large ones. This binding is often very tight and specific, and can be made use of in separation procedures. The method is called 'affinity chromatography', and exploits the affinity of the protein for its natural ligand. The principle is illustrated in **Figure 4**. The adsorbent is designed so that it selects out only those proteins that bind to that particular ligand. The proteins may subsequently be eluted using some solute that disrupts the interaction, often just salt or more specifically with the natural ligand, free in solution.

Affinity Methods Associated with Recombinant Proteins

The most significant development in the past decade for purifying proteins has been the use of molecular

biology techniques not only to express the desired protein in large amounts, but also to modify it in a way that makes its purification easy. This is achieved by making the protein longer with extra amino acid residues (polypeptide) that can be recognized by an affinity column. The product is called a fusion protein. There are many systems available, and the process is made easy by commercially available expression systems that automatically add the desired polypeptide. In some cases, the addition may be fewer than ten amino acids. In other cases it is a whole extra protein, which folds into an active shape while linked to the desired protein being expressed. Often the overall expression level is even higher with these 'fusion products' than with the unmodified protein, because the expression of the fusion portion has been optimized in designing the vector.

After purifying the fusion protein, it may be necessary to remove the fusion portion. This can be done with selective proteases, though these usually still leave a few extra amino acids on the end. One system involving an intein, or self-splicing protein, enables release of exactly the desired protein with no gain or loss of amino acid.

Integrated Purification Schemes

Purification of proteins, even when using the highly selective affinity methods, usually requires more than one step, with the extra steps carried out sequentially. The starting material is the most bulky stage, the crudest and least pure sample of the desired protein, and the first separation step needs to be able to deal with such material. A traditional scheme is to use salt (ammonium sulfate) fractionation first, then an ion exchange column, followed by gel filtration. Each of these steps exploits a different property of the proteins, so when combined they give a good chance of high selectivity. Repeated use of one particular procedure, e.g. ion exchange chromatography, will produce diminishing returns in terms of separation and recovery of protein.

An alternative first stage is to use an adsorbent that acts as a pseudo-affinity material and selects out the desired protein (along with many others), allowing nonprotein material to be removed. Any such adsorbent must be cheap to produce, because the crude extract can cause changes to its properties after a few uses, such as clogging or degradation. Dye adsorbents have been used for this purpose: brightly-coloured columns bind certain proteins selectively, and these can be washed off, then put through other steps such as ion exchange and/or gel filtration.

Table 2 Purification of an enzyme using three different procedures: dye adsorbent chromatography exploiting surface characteristics; ion exchange chromatography exploiting charge differences; and gel filtration to separate by size. The enzyme was xylulokinase from a thermophilic *Bacillus* sp. (author's unpublished results). Specific activity is in units of enzyme activity per milligram of protein. Nearly 200-fold purification was achieved, and the final enzyme was judged to be about 95% pure. This implies that the xylulokinase enzyme made up just 0.5% of the total protein in the original extract.

Purification step	Volume (mL)	Amount of protein (mg)	Amount of enzyme (units)	Specific activity	Purification (x-fold)	Recovery (%)
Extract	50	650	290	0.45	1	100
Off dye adsorbent	29	36	208	5.8	13	72
Off anion exchange	15	7.5	150	20	44	52
(NH ₄) ₂ SO ₄ precipitated	0.65	2.2	150	66	147	52
Gel filtration	2.0	1.4	120	86	190	41

The final stage in a protein purification will often be a high resolution step such as HPLC. Any asymmetry of the final peak might indicate that impurities are still present.

A purification procedure ideally results in a good yield of a 'pure' protein. If the final product is an enzyme it is relatively easy to determine how much remains at the final stage, compared with the amount in the crude extract, by measuring its activity.

Sacrifices of recovery for purity (or vice versa) during the procedure will need to be made, depending on the relative importance of these two factors. Table 2 illustrates a typical purification of an enzyme, with a respectable recovery of activity and an end product that was analytically close to homogeneous.

Analytical Separations

At various stages, but more particularly at the end, one needs to know how close to purity the protein fraction is. Of many different analytical techniques that have been used, one is universally employed. This is known as SDS-PAGE, which stands for sodium dodecyl sulfate-polyacrylamide gel electrophoresis. The gel (polyacrylamide) has pores that are similar in size to the protein molecules, and the mixture of proteins is forced through the gel by an electric field. First the proteins are fully denatured by treatment with the anionic detergent sodium dodecyl sulfate, which binds to all the proteins and confers on them a negative charge proportional to their size. The smaller proteins move through the gel relatively easily, but the larger ones are retarded by the lack of pores large enough to move through. Consequently there is a separation of components according to size, in a logarithmic way similar to that observed for gel filtration (see Figure 3). The individual components remain in tight bands; as a consequence proteins that differ in size by only 3–5% can be completely separated. This sharp resolution is thus able to detect small amounts of impurity, and a judgement can be

made on the absolute purity of the sample. One further feature is that, as with gel filtration, the distance moved by an unknown protein can be compared with known standards and the unknown molecular weight determined to within about 5% accuracy. The amount of protein required is only about 1 µg or less, depending on the detection (staining) method. Capillary electrophoresis systems can be even more sensitive and accurate for analytical work.

Size Exclusion Chromatography of Polymers

B. Trathnigg, Karl-Franzens-University,
Graz, Austria

Copyright © 2000 Academic Press

Obviously, elution volumes in ideal SEC are always smaller than the void volume of the column:

$$V_i < V_e < V_0 = V_i + V_p$$

$$0 < K_{\text{SEC}} < 1$$

Introduction

In the characterization of polymers, size-exclusion chromatography (SEC) has become a standard technique for determining molar mass averages and molar mass distributions (MMD) of polymers. The principle of SEC is easily understood: owing to limited accessibility of the pore volume within the particles of the column packing, polymer molecules are separated according to their hydrodynamic volumes, which can be correlated to their molar mass. Unfortunately, this is not as easy and simple as it looks. There are numerous sources of error and pitfalls in the separation, in the detection and in the treatment of the raw chromatographic data.

Separation

In SEC, the separation should be solely governed by size exclusion, which need not always be the case. Let us first consider the ideal case, in which size exclusion does govern the separation.

Separation by Exclusion

Elution volumes in ideal SEC are limited to a narrow range (smaller than the column volume). It is clear, that no fraction of the sample can be eluted, before the interstitial volume V_i (i.e. the volume of the solvent outside the particles of the column packing) has passed the column.

- Large molecules, which have no access to the pores (exclusion limit), are eluted at V_i .
- Small molecules, which have access to the entire pore volume V_p , will appear at the void volume V_0 , which is the sum of the interstitial volume V_i and the pore volume V_p .
- Molecules of a size between these extremes have access only to a part of the pore volume, hence they will be eluted with an elution volume V_e between V_i and V_0 , which is determined by K_{SEC} , the equilibrium constant of a sample in ideal size exclusion chromatography:

$$V_e = V_i + K_{\text{SEC}} V_p$$

The relation between V_e and the molar mass of a polymer is determined by calibration, as will be discussed later.

Exclusion Versus Nonexclusion Effects

The equilibrium constant of a chromatographic separation can be correlated with thermodynamic parameters.

The driving force for a separation at the (absolute) temperature T is the change in Gibbs Free Energy ΔG , which results from the changes in enthalpy (ΔH) and entropy (ΔS), respectively:

$$\Delta G = \Delta H - T\Delta S = -RT \ln K$$

In ideal SEC, which should be governed solely by entropy, ΔH should equal zero, and the equilibrium constant K_{SEC} should be given by:

$$K_{\text{SEC}} = e^{\Delta S/R}$$

while the equilibrium constant of adsorption chromatography (in the absence of exclusion) is determined by the enthalpy (typically, K_{LAC} is much larger than unity):

$$K_{\text{LAC}} = e^{-\Delta H/RT}$$

However, adsorption effects cannot always be completely eliminated. The distribution coefficient will then be given by:

$$K = K_{\text{SEC}} K_{\text{LAC}}$$

Under certain conditions, entropic and enthalpic phenomena will compensate each other, and K will equal 1. In this case, which is called the critical point of adsorption, all chains of the same structure are eluted in a narrow peak and separation of groups different from the repeating unit (end groups, branching sites, etc.) can be achieved.

This effect can be used in the analysis of functional oligomers or block copolymers. Even in the absence of adsorption phenomena there may be

another effect, which is called secondary exclusion. It originates from (electrostatic) repulsion of polar groups and has nothing to do with molar mass. The equilibrium constant K can then be divided into contributions from ideal size exclusion and from repulsion:

$$K = K_{\text{SEC}}K_{\text{rep}}$$

If interactions with the stationary phase also occur, the elution volumes will depend on all three distribution coefficients:

$$V_e = V_i + V_p K_{\text{SEC}} K_{\text{rep}} K_{\text{LAC}}$$

In ideal SEC, repulsion and adsorption should be absent, hence K_{rep} as well as K_{LAC} should equal unity.

The column(s)

Unlike other modes of high-performance liquid chromatography (HPLC), separation efficiency comes only from the stationary phase, while the mobile phase should have no effect. The whole separation occurs within the volume of the pores, which typically equals approximately 40% of the total column volume. This means, that long columns, or often sets of several columns are required. Different types of SEC columns are available, which are either based on porous silica or on semi-rigid (highly cross-linked) organic gels, in most cases copolymers of styrene (St) and divinylbenzene (DVB).

Table 1 lists some commercially available column packings for nonaqueous SEC. In general, silica-based packings are quite rugged, while organic packings must be handled with care. Typically, the separation range of a column covers approximately two decades of molar mass (e.g. from 1×10^4 to 1×10^6). Most producers also offer mixed bed columns covering a much wider range.

Obviously, a good separation is only one part of a good analysis. Another crucial point is the detection of the fractionated sample leaving the column.

Detection

Among the numerous HPLC detectors, only a limited number can reasonably be applied in SEC. One has to distinguish between concentration detectors and molar mass detectors.

- The response of a *concentration detector* is determined by the concentration of the solute in the mobile phase.
- The response of a *molar mass detector* depends on molar mass of the solute, as well as on concentration.

At least one concentration-sensitive detector has to be used in an SEC system. In the analysis of copolymers, a second concentration-sensitive detector is required, the sensitivity of which towards the components of the polymer differs from that of the first detector.

Concentration-sensitive Detectors

The concentration detectors most frequently used in SEC of polymers are the UV and the RI detectors. Infrared (IR) detection suffers from problems with the absorption of the mobile phase. Two other detectors are useful in the analysis of non-UV absorbing polymers: the density detector and the evaporative light-scattering detector (ELSD).

The UV detector detects UV-absorbing groups in the polymer, which may be the repeating unit, the end groups, or both. Hence, one has to distinguish two situations. For polymers, in which the repeating units contain a chromophoric group, the response of the UV detector represents the mass eluted in a given volume interval; for polymers with chromophoric end groups, however, the response depends on the number of polymer molecules. Many chromatographers use this assumption, when they derivatize 'nonabsorbing' polymers with UV-active reagents. Detection wavelengths are in the range of 180–350 nm but many SEC solvents allow detection only above a wavelength of 250 nm. Diode array detectors allow the measurement of an entire UV-spectrum at any point of the chromatogram, which is useful in SEC of copolymers.

Table 1 Column packings for nonaqueous size exclusion chromatography

Producer	Packing	Material
Rockland Technologies	Zorbax PSM	Porous silica microspheres
Shodex	Asahipak GF HQ	Highly crosslinked polyvinyl alcohol
Macherey-Nagel	Nucleogel GPC	St-DVB copolymer
Merck	LiChrogel PS	St-DVB copolymer
Phenomenex	Phenogel	St-DVB copolymer
Polymer Laboratories	PL gel	St-DVB copolymer
Waters	Styragel HR, HT, MW, Ultrastayragel	St-DVB copolymer
Jordi	Jordi GPC	100% DVB polymer

The ELSD detects any nonvolatile components of a sample. In this instrument, the eluate is nebulized and the solvent evaporated from the aerosol. Each droplet containing nonvolatile material will form a particle, which scatters the light of a transversal light beam. The response of this instrument for copolymers is, however, unclear – it depends on various parameters and the nature of these dependencies is rather complex. Moreover, lower oligomers may be strongly underestimated.

The refractive index (RI) detector exists in various modifications. It is the most common instrument in SEC besides the UV detector.

The density detector, which has been developed in the author's group, uses the principle of the mechanical oscillator. The measuring cell of this instrument is an oscillating, U-shaped capillary, the period of which depends on its reduced mass, and thus on the density of its contents. The signal of the density detector is thus inherently digital, and its response is integrated over each measuring interval.

Molar Mass-sensitive Detectors

The response of such a detector depends on the concentration and also on the molar mass of the fraction, hence it has to be combined with a concentration-sensitive detector. The following types of molar mass-sensitive detectors are on the market: low angle light scattering detectors (LALLS); multi-angle light scattering detectors (MALLS); and differential viscosimeters.

From light-scattering detection, the absolute molar mass distribution (MMD) can be determined directly but no information is obtained on polymer conformation. However, SEC with viscosity detection yields the intrinsic viscosity distribution (IVD). Hence it makes sense to combine a light-scattering detector with a viscosimeter detector. In light-scattering detectors (LALLS, MALLS) the light of a laser beam is scattered by the dissolved polymer coils in the measuring cell and the intensity of the scattered light is measured at angles different from zero.

The (excess) intensity $R(\theta)$ of the scattered light at the angle θ is correlated to the weight average of molar mass M_w :

$$\frac{K^*c}{R(\theta)} = \frac{1}{M_w P(\theta)} + 2A_2c$$

where c is the concentration of the polymer, A_2 is the second virial coefficient, and $P(\theta)$ describes the scattered light's angular dependence. K^* is an

optical constant containing Avogadro's number N_A , the wavelength λ_0 refractive index n , and the refractive index increment dn/dc :

$$K^* = 4\pi^2(dn/dc)^2/(\lambda^4 N_A)$$

In a plot of $K^*c/R(\theta)$ versus $\sin^2(\theta/2)$, M_w can be obtained from the intercept and the radius of gyration from the slope. It must be mentioned, that dn/dc of copolymers may vary strongly with composition.

Viscosity detectors yield the intrinsic viscosity $[\eta]$, the so-called limiting viscosity number, which is defined as the limiting value of the ratio of specific viscosity ($\eta_{sp} = (\eta - \eta_0)/\eta_0$) and infinitely low concentration c :

$$[\eta] = \lim_{c \rightarrow 0} \frac{\eta - \eta_0}{\eta_0} = \lim_{c \rightarrow 0} \frac{\eta_{sp}}{c}$$

Since the concentrations in SEC are typically very low, $[\eta]$ can be approximated by η_{sp}/c . In viscosity detection, one has to determine the viscosity, η , of the sample solution as well as the viscosity, η_0 , of the pure mobile phase.

This is typically done by measuring the pressure drop across a capillary; the pressure drop is proportional to the viscosity of the streaming liquid (using a differential pressure transducer). The problems of single capillary viscometers (SCV) are obvious: the viscosity changes, $\Delta\eta = \eta - \eta_0$, will typically be very small compared to η_0 . Moreover, pressure differences due to pulsations of a reciprocating pump will be much larger than those resulting from the viscosity change caused by the eluted polymer.

A better, but still not perfect approach is the use of two capillaries in series, each of which is connected to a differential pressure transducer and a sufficiently large hold-up reservoir in between. Pulsations will be eliminated in this setup, because they appear in both transducers simultaneously.

A sophisticated approach is used in a differential viscometer, which is commercially available from Viscotek. In this instrument, four capillaries are arranged similar to a Wheatstone bridge. The detector measures the pressure difference ΔP at the differential pressure transducer between the inlets of the sample capillary and the reference capillary, which have a common outlet, and the overall pressure P at the inlet of the bridge. The specific viscosity, $\eta_{sp} = \Delta\eta/\eta$ is thus obtained from $\Delta P/P$.

Data Processing

Provided that the separation itself is reliable (which cannot always be taken for granted), the subsequent transformations are subject to errors:

- Elution time to elution volume: because of the logarithmic relation between molar mass and elution volume, small changes of the flow rate can cause large errors in molar mass.
- Elution volume to molar mass: the molar mass of a fraction can be obtained either from calibration or from a molar mass-sensitive detector (in addition to the concentration detector).
- Detector response to polymer concentration: this requires a sufficiently wide linear range, a well-defined response of the detector(s) along the entire peak (i.e. for all molar masses within the MMD) and, in the case of copolymers, a second concentration detector.

Determination of Elution Volumes

The absolute flow rate can be obtained by measuring the time to fill a calibrated flask or by weighing the solvent passing the system in a defined time.

The knowledge of the absolute flow rate is, however, not completely necessary as long as flow rate variations are compensated by using an internal standard. The corrected flow rate is obtained from the ratio of the elution times of this standard peak. Such a correction only works well, if the flow rate is sufficiently constant within the entire chromatogram.

Determination of Molar Mass

Unless a molar mass-sensitive detector is used, one has to determine the molar mass of a fraction eluting at the volume V_e from a calibration, which can be obtained in different ways.

Calibration with narrow standards If a series of standards with a narrow MMD is available, their elution volumes must be determined to establish a calibration from which the molar mass for a given elution volume may be obtained. In the early years of SEC, a linear relation between $\log M$ and V_e was assumed, which is, however, only a first approximation, the quality of which depends very strongly on the columns:

$$\log M = A + BV_e$$

where A and B are constants, which can be determined very easily by linear regression. For many columns, the calibration line is, however, sigmoidal rather than linear (Figure 1). In this case, a polynomial fit matches the experimental points much better:

$$\log M = A + BV_e + CV_e^2 + DV_e^3 + EV_e^4 + \dots$$

Figure 1 SEC calibration of a mixed bed column (Phenogel M, 7.8×600 mm) in 2-butanone at 25°C .

The order of the polynomial fit is, however, critical in some cases: if the number of data points (i.e. the number of standards) is too small, a fit of a too high order may produce an erroneous calibration line.

It must also be mentioned that there can be considerable differences between the calibration lines for different polymers on the same column in the same mobile phase.

This is especially important in the analysis of copolymers or polymer blends. Consequently, different molar masses will elute at the same volume, when a mixture of two homopolymers is analysed by SEC. The elution volume of a copolymer should be between the elution volumes of the homopolymers of the same molar mass.

If the composition of the copolymer at each point of the peak is known, a good approximation will be achieved by interpolation between the calibration lines. Calibration with narrow standards can be applied to many types of polymers, because appropriate standards have become commercially available for many polymers. In the low molecular range, additional data points can be taken from the maxima of oligomer peaks, which are at least partly resolved.

Different approaches have been described in the literature for the analysis of samples, for which no narrow MMD standards are available.

Calibration with broad standards If a well-characterized sample with broad MMD is available, different procedures may be used to establish a calibration fitting these averages.

The integral-MMD method can be applied if the entire MMD of the standard is known with high accuracy (which is, however, seldom the case). The method assumes, that the MMD of the sample can be described by the most probable distribution function and matches the calibration to this distribution. No assumptions on the shape of the calibration are made and the precision of the method is rather poor.

If only the molar mass averages of the sample are known from independent methods (light scattering or osmometry), linear calibration methods can be applied. The assumption of a linear calibration may, however, lead to erroneous results.

Universal calibration A very elegant approach is based on the fact, that in SEC the elution volume V_e of a polymer depends on its hydrodynamic volume, which is proportional to the product of its molar mass M and intrinsic viscosity $[\eta]$.

In a plot of $\log(M[\eta])$ versus V_e (obtained on the same column), identical calibration lines should be found for two polymers (1 and 2), which can be

considered as universal calibration:

$$M_1[\eta]_1 = M_2[\eta]_2$$

The intrinsic viscosity is a function of molar mass, which is described by the Mark-Houwink relationship, where K and a are constants for a given polymer in a given solvent at a given temperature:

$$[\eta] = KM^a$$

Combination of the equations above yields:

$$K_1 M_1^{a_1+1} = K_2 M_2^{a_2+1}$$

If a column has been calibrated with one polymer (1), the calibration line for another polymer (2) can be calculated, provided that the constants K and a are known for both polymers with sufficient accuracy:

$$\ln M_2 = \frac{1}{1+a_2} \ln \frac{K_1}{K_2} + \frac{1+a_1}{1+a_2} \ln M_1$$

The concept of universal calibration will also provide an appropriate calibration for polymers, for which no narrow standards exist.

The problem is, however, that the accuracy of K and a is limited even with polymers for which a sufficient number of well-defined standards exists: there are very large variations in the values reported in literature even in this case, as can be seen from Table 2.

^aKurata M, Tsunashima Y, Iwama M and Kamada K (1975) In: Brandrup J and Immergut E (eds), *Polymer Handbook*. New York: Wiley, p. IV-1.

Figure 2 SEC calibration of a mixed bed column (PL Microgel M, 7.8×600 mm) in chloroform at 25°C .

The consequences can be dramatic, as is shown in Figures 1 and 2. In 2-butanone, the calibration functions obtained on a Phenogel MTM (Phenomenex) (mixed bed) column are quite different for polystyrene (PS) and poly(methyl methacrylate) (PMMA) (Figure 1). While the PS calibration is rather sigmoidal, a nearly linear calibration is found for PMMA. Using the MHS parameters from the literature (Table 2), both calibrations are closer, but there are still considerable differences.

In Figure 2, the calibrations of a PL Microgel MTM (Polymer Laboratories) (mixed bed) column are shown, which were obtained with PS, PMMA and PEG standards in chloroform. For PS and PMMA, very nice linear calibration functions are found, which almost coincide, while the attempt to establish a universal calibration for PEG with literature data makes the deviations even larger.

Quantification in SEC

After the first two transformations – time to volume and volume to molar mass – have been performed, there remains the third transformation – detector response to amount of polymer in a fraction – which can also be subject to errors, depending on the nature of the samples. In the following section, the particular

problems are referred to with respect to the type of polymer to be analysed.

Molar Mass Dependence of Response Factors

In chromatography of polymers, the most frequently used detectors are the UV and the RI detector. Recently, we have introduced the density detector, which is very useful in the analysis of non-UV absorbing polymers.

The UV-detector responds to UV-absorbing groups in the polymer, which may be the repeating unit, the end groups, or both.

RI and density detectors measure a property of the entire eluate, that means, they are sensitive to a specific property of the sample (the RI increment or the apparent specific volume, respectively). It is a well known fact, that specific properties are related to molar mass:

$$x_i = x_\infty + \frac{K}{M_i}$$

where x_i is the property of a polymer with the molecular weight M_i , x_∞ is the property of a polymer with infinite (or at least very high) molecular weight, and

K is a constant reflecting the influence of the end groups.

A similar relation holds for the response factors for RI and density detection:

$$f_i = f_\infty + \frac{K}{M_i}$$

In a plot of the response factor, f_i , versus the molecular weight, M_i of a polymer homologous series (with the same end groups) one will obtain a straight line with the intercept f_∞ (the response factor of a polymer with very high molecular weight, or the response factor of the repeating unit) and the slope K , which represents the influence of the end groups.

Once f_∞ and K have been determined, the response factors for each fraction eluting from the column can be calculated using this equation (with the molecular weight obtained from the SEC calibration).

One more problem concerns preferential solvation: when a polymer is dissolved in a mixed solvent, the composition of the latter within the coils can be different from outside because of different interactions of the polymer chain with the individual components of the solvent. When the sample is separated on the column from the zone where the solvent would elute, a system peak (vacancy peak) appears, which is due to the missing component of the mobile phase. Obviously, the missing amount of solvent in the system peak appears in the peak of the polymer, the area of which is now different from what it would be in absence of preferential solvation.

Although this effect has been known for a long time, it is often neglected by chromatographers because they consider their mobile phase to be a 'pure' solvent, which is, however, generally not the case: even HPLC-grade solvents are seldom more than 99.5% pure and, if so, they take up moisture from the air, form peroxides and so on. The content of a second component (e.g. water or a stabilizer) can thus be much higher than the concentration of the sample when it leaves the column and enters the detector.

If the polarity of the end groups of a polymer is considerably different from that of the repeating units, their contribution cannot be neglected, and preferential solvation depends on molar mass.

Copolymers and polymer blends In the analysis of copolymers, the use of multiple detectors is generally inevitable. If the response factors of the detectors for the components of the polymer are sufficiently different, the chemical composition along the MMD can be determined from the detector signals.

When multiple detection is used, one has to be aware of errors arising from peak spreading between the detectors and from inaccurate shift time (just as in combinations with molar mass detectors). Typically, a combination of UV and RI detection is used, but other detector combinations have also been described.

If the components of the copolymer have different UV-spectra, a diode array detector will be the instrument of choice. However, one has to keep in mind, that nonlinear detector responses may also occur with UV detection. In the case of non-UV absorbing polymers, a combination of RI and density detection yields the desired information on chemical composition. The ELSD is not equally suitable because of unclear response to copolymers.

The principle of dual detection is quite simple: when a mass m_i of a copolymer, which contains the weight fractions w_A and w_B ($w_B = 1 - w_A$) of the monomers A and B, is eluted in the slice i of the peak, it will cause a signal $x_{i,j}$ in the detectors, the magnitude of which depends on the corresponding response factors $f_{j,A}$ and $f_{j,B}$, where j denotes the individual detectors:

$$x_{i,j} = m_i(w_A f_{j,A} + w_B f_{j,B})$$

The weight fractions w_A and w_B of the monomers can be calculated using:

$$\frac{1}{w_A} = 1 - \frac{\left(\frac{x_1}{x_2} * f_{2,A} - f_{1,A}\right)}{\left(\frac{x_1}{x_2} * f_{2,B} - f_{1,B}\right)}$$

Once the weight fractions of the monomers are known, the correct mass of polymer in the slice can be calculated using:

$$m_i = \frac{x_i}{w_A * (f_{1,A} - f_{1,B}) + f_{1,B}}$$

and the molecular weight, M_C of the copolymer is obtained by interpolation between the calibration lines of the homopolymers:

$$M_C = M_B + w_A * (M_A - M_B)$$

wherein M_A and M_B are the molecular weights of the homopolymers, which would elute in this slice.

A typical example is given in **Figure 3**, which shows the MMD of a block copolymer of ethylene oxide (EO) and propylene oxide (PO), as obtained by SEC (in chloroform) with coupled density and

Figure 3 MMD and chemical composition of an EO-PO block copolymer (Figure 2), as determined by SEC in chloroform with density and RI detection. PEG + PPG.

RI detection. As can be clearly seen, this sample obviously contains polypropylene glycol as a by-product.

The interpolation between the calibration lines cannot be applied to mixtures of polymers (polymer blends): if the calibration lines of the homopolymers are different, different molecular weights of the homopolymers will elute at the same volume.

The universal calibration is not capable of eliminating the errors originating from the simultaneous elution of polymer fractions with the same hydrodynamic volume, but different composition and molar mass. Obviously it is feasible to use a combination of molar mass-sensitive detectors, such as a LALLS, MALLS and viscosity detector with two concentration detectors, from which the (average) composition for each fraction can be obtained, and thus the amount of polymer in the fraction. Nevertheless, discrimination of copolymers and polymer blends is impossible with one-dimensional chromatography.

Conclusion

The potential of SEC in polymer characterization is very great, especially when this technique is combined with other modes of liquid chromatography. Multiple detection is in most cases inevitable: combinations of different concentration detectors provide information on copolymer composition, and molar mass-sensitive detectors can eliminate errors with inadequate calibrations. For complex polymers (with distributions in molar mass, chemical composition,

functionality, etc.) one-dimensional techniques can, however, only provide part of the desired information. For these samples, multidimensional separations will be required. In most cases, one of the dimensions which will be SEC, while the other(s) could be gradient HPLC, or liquid chromatography at the critical point of adsorption (LCCC).

Chromatography is classified into gas chromatography (GC), supercritical fluid chromatography (SFC) and liquid chromatography (LC), depending on the physical properties of the mobile phase. Since the mobile phase in GC is a gas such as helium or nitrogen that does not have any interaction with analytes and carries them through the column, it is called a carrier gas. On the other hand, the mobile phase in LC dissolves analytes and will interact with them. Therefore, the mobile phase in LC significantly affects the selectivity of the separation. Although there are many options to improve the selectivity of the separation in LC, experience and knowledge are required for optimization. In SFC a high density gas is employed as the mobile phase, where the temperature and pressure in the column are higher than the critical values of the mobile phase employed. The mobile phase in SFC has intermediate properties between those in GC and in LC. **Table 1** compares physical properties of the mobile phase in three chromatographic modes. The density, viscosity and diffusion coefficients determine the solubility of analytes, permeability of the column and the speed of analysis, respectively.

The effect of temperature on retention behaviour in SFC on a thermodynamic basis has been discussed elsewhere, as well as thermodynamic retention behaviour in open tubular capillary SFC. It was found that LC-like or GC-like retention mechanisms were involved in the supercritical temperature region, depending on the column temperature and the inlet pressure.

Generally, separations in GC are performed using completely different systems from those in LC. The separation system in SFC is a hybrid between GC and LC. However, it should be noted that the

temperature and pressure can control the physical properties of the mobile phase. If these two parameters are controlled, separations can be obtained in any three chromatographic modes using a single chromatographic system. Both plunger and syringe pumps can be used for this purpose.

Instrumentation

When an LC-like detector such as a UV detector is used, a two-pump system is favoured. The two pumps are operated in the pressure control mode, and the inlet and the outlet pressures are controlled independently, so that the pressure drop across the column can be controlled.

When a GC-like detector such as a flame ionization detector (FID) is used, the two-pump system is not applicable and a single-pump system is used. A low dead-volume restrictor is generally employed in this case to maintain an appropriate pressure and to avoid additional dispersion of analytes.

The oven should be capable of negative as well as positive temperature programming. Negative temperature programming is useful in SFC, as shown below.

Open tubular capillary columns with various immobilized stationary phases are commercially available. The smallest diameter commercially available is around 50 μm . On the other hand, packing materials with 3–50 μm particle diameters for LC can be used for packed capillary columns, and fused silica tubing or glass-lined stainless-steel tubing are available. Conventional packed columns (1–5 mm i.d.) are still used most often in SFC, but they do not fit into the compromise that constitutes universal chromatography.

Temperature Effect

Figure 1 shows the effect of column temperature on retention behaviour using a packed column and carbon dioxide or methanol as the mobile phase. The relationships between the logarithm of the retention factor of aromatic hydrocarbons, $\log k$, and the recip-

Table 1 Comparison of physical properties of the mobile phase in three chromatographic modes

Chromatography	Density (g cm^{-3})	Viscosity ($\text{g cm}^{-1} \text{s}^{-1}$)	Diffusion coefficient ($\text{cm}^2 \text{s}^{-1}$)
Gas chromatography	10^{-3}	$(0.5\text{--}3.5) \times 10^{-4}$	0.01–1.0
Supercritical fluid chromatography	0.2–0.9	$(0.2\text{--}1.0) \times 10^{-3}$	$(0.1\text{--}3.3) \times 10^{-4}$
Liquid chromatography	0.8–1.0	$(0.3\text{--}2.4) \times 10^{-2}$	$(0.5\text{--}2.0) \times 10^{-5}$

Figure 1 Relationships between the logarithm of the retention factor of aromatic hydrocarbons ($\log k$) and the reciprocal of absolute column temperature (T^{-1}). Columns: Develosil ODS-5 (5 μm ODS), 150 \times 0.5 mm i.d. (1–6) or 145 \times 0.3 mm i.d. (7). Mobile phase: carbon dioxide (1–6) or methanol (7). Inlet pressure: 12 MPa (1–6) or 9.0 MPa (7). CT, Critical temperature. Samples: 1 = biphenyl; 2 = fluorene; 3 = *o*-terphenyl; 4 = pyrene; 5 = 9-phenylanthracene; 6 = triphenylene; 7 = pyrene. Detector: UV.

reciprocal of absolute column temperature, $1/T$, are shown in the figure with an inlet pressure of 12 MPa for carbon dioxide and 9.0 MPa for methanol. It should be noted that the pressure in the column is higher than each critical pressure, e.g. 7.38 MPa for carbon dioxide and 7.95 MPa for methanol. The critical temperatures of carbon dioxide and methanol are denoted as CT in the figure. At each higher critical temperature region, the retention factor increases with decreasing column temperature, while at each lower critical temperature region it decreases with decreasing column temperature. When the mobile phase is liquid, i.e. at a temperature lower than the CT, the retention factor increases with decreasing column temperature, as shown in the case of the methanol mobile phase.

It should be noted that the density of the mobile phase decreases with increasing temperature. The density of carbon dioxide is shown in Figure 2.

It is possible to distinguish a region in which the retention factor decreases with decreasing column temperature (SFC region) from one in which it increases with decreasing column temperature (high pressure GC region). The former region appears at lower supercritical temperatures, in which solvation

of the analyte by the mobile phase is dominant, while the latter region appears at higher supercritical temperatures, in which the contribution of volatility is

Figure 2 Density of carbon dioxide.

Figure 3 (A) Negative and (B) positive temperature programming of dialkyl phthalates on an SB-octyl-50 column. Column: SB-octyl-50 (5% *n*-octylmethylpolysiloxane), 10 m \times 50 μ m i.d. Mobile phase: carbon dioxide. Inlet pressure: 12 MPa. Samples: 1 = dimethyl; 2 = diethyl; 3 = diisobutyl; 4 = di-*n*-propyl; 5 = diisobutyl; 6 = di-*n*-butyl; 7 = diheptyl; 8 = di-2-ethylhexyl; 9 = dinonyl phthalate. Initial temperature: 130°C. Temperature programming: (A) $-10^{\circ}\text{C min}^{-1}$ for 4 min, and $-5^{\circ}\text{C min}^{-1}$ for the rest of the analysis; (B) $+10^{\circ}\text{C min}^{-1}$ for 2 min, $+20^{\circ}\text{C min}^{-1}$ for the next 4.5 min and kept at 240°C for the rest of the analysis. Wavelength of UV detection: 225 nm. (Reproduced with permission from Takeuchi *et al.* (1988). Temperature programming elution in capillary supercritical fluid chromatography. *Chromatographia* 25: 127.)

dominant. In the intermediate temperature region, both contributions are involved. In addition, non-volatile analytes cannot be eluted in the high pressure GC region, but they are eluted in the SFC and LC regions. It is clear that both SFC and high pressure GC separations can be demonstrated by changing the column temperature. Negative temperature programming is useful for the former, while positive temperature programming is useful for the latter mode.

Figure 3 demonstrates the separation of dialkyl phthalates using negative and positive temperature programming using an SB-octyl-50 open tubular capillary column and a UV detector. Both temperature programmes are started from the same temperature, i.e. 130°C. The programming rate is changed during the separation so that optimum resolution can be achieved in a reasonable time. The pressure is kept constant at 12 MPa during the separation. In Figure 3(A), SFC-like separation is demonstrated, while GC-like separation is demonstrated in Figure 3(B).

Figure 4 Log k versus $1/T$ for hexane mobile phase. Column: Develosil-60-10 (10 μ m silica gel), 300 \times 0.5 mm i.d. Mobile phase: hexane. Inlet pressure: 0.49 MPa. Outlet pressure: ambient pressure. CT, Critical temperature. Samples: \bullet = benzene; \blacktriangle = naphthalene; \blacksquare = anthracene. Wavelength of UV detection: 254 nm. (Reproduced with permission from Takeuchi *et al.* (1988). Micropacked column GC with vapor of organic substance as the mobile phase. *Chromatographia* 25: 994.)

GC Using an LC System

In GC permanent gases are usually employed as the carrier gas. The vapour of an organic substance can also be used as the mobile phase for GC when the pressure in the column is lower than the vapour pressure at the operating temperature. In contrast, when the pressure in the column is higher than the vapour pressure, analytes are subjected to LC-mode separation. By controlling the column temperature and pressure, it is possible to demonstrate both GC and LC using a single LC system. It is convenient to use a micro-LC system because the heat capacity of micropacked columns of 0.2–0.5 mm i.d. is small.

Figure 4 shows the relationships between the logarithm of the retention factor and the reciprocal of the absolute column temperature when hexane and silica gel are used as the mobile and stationary phases. In Figure 4 the inlet pressure is 0.49 MPa, while the outlet pressure is atmospheric. The mobile phase is liquid when passing through the flow cell of the UV detector. The critical temperature and pressure of hexane are 234°C and 3.0 MPa, respectively. The critical temperature of hexane is denoted as CT in the figure. It should be noted that the pressure in the column is lower than the critical pressure. At higher

Figure 5 GC separation of alkylbenzenes at an inlet pressure of 0.49 MPa using hexane as a carrier gas. Column: Develosil-60-10 (10 μm silica gel), 300 \times 0.5 mm i.d. Mobile phase: hexane. Peaks: 1 = benzene; 2 = toluene; 3 = naphthalene; 4 = *o*-xylene; 5 = *n*-propylbenzene; 6 = mesitylene; 7 = sec.-butylbenzene; 8 = *n*-butylbenzene; 9 = *n*-amylbenzene. Wavelength of UV detection: 254 nm. (Reproduced with permission from Takeuchi *et al.* (1988). Micropacked column GC with vapor of organic substance as the mobile phase. *Chromatographia* 25: 995.)

temperatures linear relationships between $\log k$ and $1/T$ are observed, where the GC separation mode is involved. Since the applied pressure is lower than the critical pressure, the hexane vaporizes at a temperature lower than the critical temperature. When the outlet pressure is higher than the vapour pressure at the operated temperature, the hexane is liquid in the column and analytes are separated in the normal-phase LC mode; almost linear relationships between two parameters are observed. At some intermediate temperature the retention factor drastically changes with column temperature, where the state of the hexane in the column changes from liquid to gas, and both liquid and gaseous hexane exist at the boundary region in the column.

Figure 5 demonstrates GC separation of alkylbenzenes using hexane vapour as the mobile phase. The analytes are monitored by a UV detector at 254 nm. The mobile phase is liquefied while passing through a 60 cm \times 70 μm i.d. capillary tube connecting the separation column and the flow cell of the detector. The capillary tubing is kept at ambient temperature.

GC Using LC Columns

Micropacked columns for LC can be applied to GC separation of hydrocarbons. When a glass-lined stainless-steel tube of 30 cm \times 0.3 mm i.d., packed with 5 μm alkyl-modified silica, is employed as the separation column, a microvalve injector for LC should be used because of the large pressure drop across the column.

Figure 6 demonstrates the separation of C_6 – C_{20} straight-chain hydrocarbons using carbon dioxide carrier gas, an octadecylsilica (ODS) column and an FID. The inlet pressure of carbon dioxide as the carrier gas is kept at 6.2 MPa. A volume of 0.02 μL of the sample dissolved in pentane is injected. The concentration is *c.* 2% (v/v) each, corresponding to *c.* 0.3 μg each of the injected amount. The column temperature is 35°C for the initial 5 min, programmed to 230°C at a rate of 5°C min^{-1} , and then held at 230°C. As far as alkyl-modified silica packings are employed, the SFC mode will be favoured for hydrocarbons with a carbon number larger than 15 because an increase in the background signal of the FID is observed at temperatures higher than 160°C.

Figure 6 Separation of an artificial mixture of straight-chain hydrocarbons. Column: Capcell Pak C18 (5 μm ODS), 300 \times 0.3 mm i.d. Mobile phase: carbon dioxide. Inlet pressure: 6.2 MPa. Column temperature: 35°C for the initial 5 min, then programmed at 5°C min^{-1} , held at 230°C. Peaks: straight-chain hydrocarbons (the numbers refer to the carbon numbers of the corresponding straight-chain hydrocarbons), *c.* 2% (v/v) each dissolved in pentane is injected. Detector: FID. (Reproduced with permission from Takeuchi *et al.* (1989). New approach to the GC separation of hydrocarbons by using LC-like microcolumns. *Chromatographia* 27: 183.)

Figure 7 Separation of components of a kerosene. Operating conditions as in Figure 6, except for the sample and the temperature-programming rate. Column temperature: 35°C for the initial 5 min, then programmed at 3°C min⁻¹. Sample: kerosene diluted twice with pentane. (Reproduced with permission from Takeuchi *et al.* (1989). New approach to the GC separation of hydrocarbons by using LC-like microcolumns. *Chromatographia* 27: 184.)

Figure 7 demonstrates the separation of the components of a kerosene. The temperature-programming rate of the column is reduced to 3°C min⁻¹. The numbers in the figure correspond to the carbon numbers of straight-chain hydrocarbons. The results offer encouragement for the use of a micropacked column as a common separation column for GC, SFC and LC.

SFC Using LC Columns

Figure 8 demonstrates the pressure-programming separation of methylphenylsiloxane oligomers using diethyl ether as the supercritical fluid. The critical temperature, pressure and density are 194°C, 3.6 MPa and 0.264 g cm⁻³, respectively. The initial inlet pressure is 4.4 MPa and the pressure is programmed at 0.1 MPa min⁻¹ for 10 min, 0.05 MPa min⁻¹ for the next 10 min and 0.025 MPa min⁻¹ for the rest of the analysis. The pressure drop across the column is maintained at 0.49 MPa using a two-pump system. The temperature is kept constant at 225°C and the analytes are detected by UV at 215 nm.

Figure 8 Pressure-programming SFC separation methylphenylsiloxane oligomers using diethyl ether as the mobile phase. Column: Develosil ODS-5 (5 µm ODS), 300 × 0.5 mm i.d. Mobile phase: diethyl ether. Initial inlet pressure: 4.4 MPa. Pressure programmed at 0.1 MPa min⁻¹ for 10 min, 0.05 MPa min⁻¹ for the next 10 min and 0.025 MPa min⁻¹ for the rest of the analysis. Pressure drop: 0.49 MPa. Temperature: 225°C. Sample: OV-17 dissolved in tetrahydrofuran. Detector: UV (215 nm). (Reproduced with permission from Takeuchi *et al.* (1987). Retention behaviour in liquid and supercritical fluid chromatography using methanol or diethyl as mobile phase. *Chromatographia* 23: 932.)

Ether is toxic and flammable. Even a small leakage of the mobile phase should be avoided for safety reasons.

Multi-mode Separations in a Single Chromatographic Run

Changing the column temperature and the pressure by using a single system allows different modes of separation to be carried out. Capillary columns, packed or open tubular, facilitate the demonstration

Figure 9 Multi-mode separation of aromatic hydrocarbons and styrene oligomers. Columns: (A) Develosil 100-5 (5 μm silica gel), 150 \times 0.5 mm i.d.; (B) 13 m \times 53 μm i.d., treated with 1 mol L⁻¹ sodium hydroxide at 55°C for 2 days. Mobile phase: diethyl ether. Initial inlet pressure: programmed as shown in the figure. Pressure drop: 0.49 MPa. Temperature: 220°C. Samples: 1 = benzene; 2 = naphthalene; 3 = anthracene; 4 = pyrene; 5 = polystyrene A-1000. Wavelength of UV detection: 220 nm. (Reproduced with permission from Ishii *et al.* (1988). Unified capillary chromatography. *Journal of High Resolution Chromatography & Chromatographic Communications* 11: 801.)

of these different modes of separation with a single chromatographic system. This is because the capillary column can achieve excellent column efficiencies. While universal chromatography allows a number of combinations to be used, it does offer more restrictions, e.g. in terms of permitted column diameters and flow rates, compared with three separate instruments.

Figure 9(A) demonstrates the separation of a prepared mixture of aromatic hydrocarbons and styrene oligomers on a silica gel packed column using the vapour of diethyl ether as the mobile phase. The analytes are isothermally separated at supercritical temperature, and the pressure is programmed so that the aromatic hydrocarbons can be separated in the GC mode prior to the SFC separation of the styrene oligomers. The pressure drop across the separation column is kept at 0.49 MPa by using a two-pump system. The inlet and outlet pressures are controlled by a microcomputer. The hydrocarbons are separated at subcritical pressure; the inlet and outlet pressures are kept at 2.45 and 1.96 MPa, respectively. The styrene oligomers are then separated by pressure-

programmed elution. The profile of the pressure programme is shown in the figure. This type of separation is of practical importance when the sample contains constituents with a wide range of volatility.

Figure 9(B) demonstrates the separation of the same mixture as in Figure 9(A) using an open tubular glass capillary column with 53 μm i.d. \times 13 m. The active surface is produced by treating soda-lime glass capillary tubing with 1 mol L⁻¹ sodium hydroxide aqueous solution at 55°C for 2 days. Nearly the same selectivity is observed between the open tubular and packed silica gel column.

Conclusion

Universal chromatography can perform the analysis of a variety of samples using a single chromatograph in which all separation modes can be selected. Universal chromatography also allows different modes of separation in series in a single run using a single chromatographic system. It allows the possibility of analysing a variety of samples with a wide range of volatilities in a single run by selecting multiple separation modes. For the more widespread use of universal chromatography appropriate detectors and stationary phases need to be developed.

Introduction

It is the role of the column to achieve separation of the components of injected mixtures. In many cases, it is also possible to accomplish *extra-column* 'separation', i.e. 'separation' by distinguishing between merged or co-eluting solutes. Selective detectors, such as the flame photometric detector, are useful in this regard, but our focus here will be directed toward separation as accomplished in the column.

The resolution equation is usually presented in one of two popular forms:

$$N_{\text{req}} = 16R_s^2[(k+1)/k]^2[\alpha/(\alpha-1)]^2 \quad [1]$$

or:

$$R_s = 1/4\sqrt{N[k/(k+1)](\alpha-1)/\alpha} \quad [2]$$

Equation [1] is used to estimate the number of theoretical plates that will be required (N_{req}) to separate any two solutes to some specified degree of resolution (R_s), as functions of the retention factor (k) of the second of those two solutes, and of their separation factor (α). These relationships will be utilized later.

Equation [2] emphasizes that resolution (i.e. the degree to which solutes are separated) is affected by only three parameters: (1) the number of theoretical plates (N); (2) solute retention factors (k); and (3) solute separation factors (α).

The number of theoretical plates is a function of the 'sharpness' of a peak, relative to the time that the solute spends in the column. The measurement is affected by the length of the solute band introduced into the column (it is assumed that this is infinitesimally small, which is never the case), the length (L) and radius (r_c) of the column, the retention factor (k) of the solute, and the average linear velocity (\bar{u}) of the carrier gas. It can also be affected by the thickness of the stationary phase film (d_f), and by solute diffusivity in the stationary phase (D_s). Small values of k yield disproportionately large values of N . This anomaly essentially disappears with values of $k \geq 5$.

The parameters affecting the solute retention factor (k) can be deduced from the inviolable relationship that must always exist between k , the distribution constant (K_c), and the column phase ratio (β):

$$K_c = \beta k \quad [3]$$

From this, it is evident that $k = K_c \times 1/\beta$, or (using the definitions in the Glossary):

$$k = c_s/c_M \times V_s/V_M \quad [4]$$

For a given solute, k varies directly with solubility of that solute in the stationary phase (e.g. the k value of pentane would, under similar conditions, be higher in a polydimethylsiloxane stationary phase than in a polyethylene glycol stationary phase). In a given stationary phase, k varies indirectly with temperature: as the temperature increases, c_s decreases and c_M increases, and k decreases in a manner that is essentially exponential.

Finally (as evidenced in eqns [3] and [4]), k varies inversely with the column phase ratio, β (or directly with $1/\beta$). In other words, solute retention factors (k) increase as the volume of column occupied by stationary phase (V_s) increases and/or the volume occupied by mobile phase (V_M) decreases. In packed columns, β is usually controlled by the stationary phase 'loading'; in the open-tubular column, β is controlled primarily through d_f , and to a smaller extent, through r_c . There are some practical limitations: where $d_f < 0.1 \mu\text{m}$, columns can exhibit excessive activity, as evidenced by 'tailing' (reversible and irreversible adsorption) of 'active' solutes. Where $d_f > 1.0 \mu\text{m}$ (or even less if $D_M < 10^{-7} \text{cm}^2 \text{s}^{-1}$), the mass transport term of the van Deemter equation (C_M) becomes limiting, and column efficiency (as reflected by N) decreases. Solute retention factors interrelate with determinations of N . Unless the gas velocity is so high that solutes can no longer undergo equilibrium partitioning (this would require extremely high velocities), k is independent of \bar{u} .

Comparisons of Packed and Open-Tubular Columns

One thousand plates per foot of column length, or approximately 3000-plates per metre, represents the best that can be expected from a packed column; although packed columns rarely achieve this value, it is often exceeded in the open-tubular system. The

length of the packed column is limited in practice to about 5 m, because the packing offers a much greater resistance to gas flow than does the open tube. As a result, the packed column can deliver a maximum of about 15 000 theoretical plates, which pales in comparison to the 150 000 to 500 000 theoretical plates that can be attained in the modern open-tubular columns. Some work has been reported using longer packed columns operated under extreme pressures, but these applications have not proven practical in a working environment.

In the open-tubular column, the theoretical maximum achievable efficiency can be estimated from the fact that:

$$H = L/N \quad [5]$$

and:

$$H_{\text{theor min}} = r_c \{[(11k^2) + 6k + 1]\}^{1/2} / [3(1 + k)^2] \quad [6]$$

It was mentioned in earlier discussions of k that small values of k exhibit disproportionately large values of N (or small values of H). If we use eqn [6] to calculate $H_{\text{theor min}}$ and $N_{\text{theor max}}$ for a 0.25 mm open-tubular column, we obtain the values shown in Table 1. A graph of these data (Figure 1) stresses the very large values of N that are obtained for small values of k . Note that this effect becomes negligible as $k \geq 5.0$.

For many years, packed columns offered a distinct advantage to the analyst concerned with the separation of highly volatile solutes, because the phase ratio (β) of the packed column is rarely greater than about 30, while the phase ratios of early wall-coated open-tubular columns were usually about 300. From eqn [3], it is evident that solute retention factors (k) will be some 10 times greater (300/30) on packed columns than on these early open-tubular columns, with all other conditions constant.

Table 1 Maximum theoretical values of the numbers of theoretical plates per metre of column length ($N \text{ m}^{-1}$) as a function of the retention factor (k) of the test solute. Values are calculated for a 0.25 mm column, and assume $D_M = 0.6 \text{ cm}^2 \text{ s}^{-1}$ and $D_S = 10^{-7} \text{ cm}^2 \text{ s}^{-1}$

k	$N (\text{m}^{-1})$, theoretical maximum
0.01	13 582
0.1	11 661
1	6 531
2.5	5 270
5	4 753
7	4 505
10	4 362

Figure 1 Graph of the data shown in Table 1, maximum theoretical values of the numbers of theoretical plates per metre of column length ($N \text{ m}^{-1}$) as a function of the retention factor (k) of the test solute. Values are calculated for a 0.25 mm column, and assume $D_M = 0.6 \text{ cm}^2 \text{ s}^{-1}$, and $D_S = 10^{-7} \text{ cm}^2 \text{ s}^{-1}$.

The number of theoretical plates that will be required to separate any two solutes is the product of three multipliers in eqn [1]: (1) the degree of resolution required [$16R_s^2$] (for baseline separation, $R_s \cong 1.5$, and this one multiplication factor becomes 36); a squared ratio of the separation factors $[\alpha/(\alpha - 1)]^2$, and a squared ratio of the retention factors $[(k + 1)/k]^2$. A highly volatile solute might exhibit $k = 0.01$ on one of these earlier open-tubular columns, and the $[(k + 1)/k]^2$ multiplier would therefore be $[101/1]^2 \cong 10\,000$. On the packed column, the phase ratio is lower, and the k of this solute (all other conditions constant) would increase by the factor $300/30 \times 0.01 \cong 0.1$. This results in the $[(k + 1)/k]^2$ multiplier becoming 121 instead of 10 000, and the number of theoretical plates required for the separation of this low- k solute has been decreased by two orders of magnitude.

Because of these relationships, the packed column user was more successful in attaining the separation of some highly volatile (low- k) mixtures that resisted separation on the wall-coated open-tubular columns of those times. The subsequent development of cross-linked and surface-bonded stationary phases permitted the manufacture of open-tubular columns with much thicker films of stationary phase – 3, 5 and 8 μm . In a 0.25 mm column, these give phase ratios of 20.8, 12.5 and 7.8, respectively, and this particular advantage of the packed column disappears. Alternatively, retention factors are usually significantly higher on porous-layer open-tubular (PLOT) columns that utilize the more retentive mode of gas–solid adsorption chromatography rather than gas–liquid partition chromatography. Even fixed gases such as argon, nitrogen, oxygen can be resolved on such columns.

Thick-film open-tubular columns suffer some distinct disadvantages, however. The exploration of this is facilitated by an examination of the van Deemter

equation. In its packed column form, this can be expressed as

$$H = A + B/\bar{u} + C\bar{u} \quad [7]$$

where A is the eddy diffusion or packing factor term, B is the longitudinal diffusion term and C is the resistance to mass transfer term. Because H is a function of $1/N$, the smaller the sum of these terms, the smaller H , and the more efficient the system. (Efficiency equations really represent the efficiency not of the column, but of the total system. A number of extra-column factors – the injection process, extra volume in the injector and detector, too low a split ratio or make-up gas flow, lag time in signal acquisition – detract from system efficiency, but efficiency equations attribute all of this to the column.) The open-tubular column has no packing, and the A term can be discarded to yield the Golay equation: $H = B/\bar{u} + C\bar{u}$. Some major differences between packed and open-tubular columns become more apparent if the C term is expanded to distinguish mass transfer from stationary phase to mobile phase (C_s) from mass transfer from mobile phase to stationary phase (C_M):

$$H = B/\bar{u} + \bar{u}[C_M + C_s] \quad [8]$$

In packed columns, most of the interior volume of the column is occupied by the particles of support material; each particle is covered with a relatively thick film of stationary phase, and there is a minuscule gas volume in the interstitial space between the particles. Hence the volume of stationary phase is large, the volume of mobile (gas) phase is small, and the packed column typically has a smaller phase ratio or β . In the packed column, the magnitude of the C term is largely a function of mass transfer from stationary to mobile phase (C_s). A solute molecule dissolved in stationary phase takes some time before it re-enters the mobile phase, where it must proceed only a minuscule distance through the carrier gas (C_M) before it again enters stationary phase. C_s is the *limiting factor* in the packed column, but C_M is trivial: hence, hydrogen, helium, nitrogen, argon-methane or carbon dioxide yield essentially the same efficiencies when used as the mobile phase in packed columns.

In the open-tubular column, a much thinner film of stationary phase is on the wall of a tube, which while usually of capillary dimension, requires solute molecules to traverse a much longer flow path through the mobile phase. Thus the transverse distance across the open-tubular column is significantly greater than the interparticle distance encountered in packed columns. As a consequence, column efficiency (and the

optimum average linear velocity of the carrier gas) varies directly with the diffusivity of the mobile phase. In the open-tubular column, C_M is the limiting factor and C_s is trivial – until we come to the thick-film open-tubular column. In this case, *both* C_s and C_M are significant; the major advantage of the open tubular column has been sacrificed, and column efficiency suffers.

An analogous limitation is encountered with low diffusivity stationary phases. In the polydimethylsiloxane stationary phase, D_s for a C_{12} compound at 150°C approximates to $1 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$. At this value, columns yield about the same efficiencies when the stationary phase film (d_f) is varied from 0.1 to $0.4 \mu\text{m}$; at $d_f > 0.4 \mu\text{m}$, the efficiencies of columns coated with this stationary phase begin to decrease. Polysiloxanes are relatively permeable, and substitutions that increase the carbon/oxygen ratio (e.g. phenyl) have an adverse effect on that permeability. This lowers the value of D_s , and column efficiency – in terms of plates per metre – decreases, unless d_f is also decreased. As an example, smaller values of d_f are desirable on columns coated with polymethylsiloxanes containing phenyl, cyanopropyl and/or polyethylene glycol-type substituents, where a significant increase in efficiency is exhibited by $0.15 \mu\text{m}$ film columns as compared to $0.25 \mu\text{m}$ films. As the rate of diffusion through the stationary phase decreases (this is a function of D_s), the distance the solute must travel through that stationary phase (a function of d_f) becomes increasingly important.

Many investigators have contributed to our progress in stationary phase and column developments. While a thorough discussion of the interrelationships and significance of these contributions is beyond the scope of this article, the Further Reading section include some of the more salient efforts in column developments.

The Stationary Phase

Many of the disparate materials employed as ‘liquid phases’ on the earliest packed columns soon proved unsatisfactory for open-tubular columns. It was eventually realized that higher temperature stabilities in open-tubular columns required highly viscous phases whose viscosity endured at the operating temperatures. With this realization, the polysiloxanes attracted interest, because they could be cross-linked to produce a semisolid gum-like phase; the term ‘stationary phase’ soon replaced ‘liquid phase’ in common usage. Columns coated with these materials exhibited higher temperature tolerances and longer lifetimes. This is another area in which a multitude of individual investigators have contributed to progress.

As discussed earlier, packed columns are typically limited to lengths that can generate 10 000 to 15 000 theoretical plates because of their higher pressure drops. With this restriction on N , the separation factor, α , becomes more critical to the packed column (eqn [2]), and α is best controlled through the choice of stationary phase. While α values do respond to changes in temperature, the direction of any given response can be predicted only for solutes whose functionalities are similar. For example, in a series of methyl ketones or a series of paraffin hydrocarbons, α values vary inversely with temperature. But if the column temperature is decreased for a sample containing a mixture of methyl ketones and paraffin hydrocarbons, one can predict only that the α of any two hydrocarbons (and that of any two ketones) will increase. The α of a mixed pair – hydrocarbon and ketone – can increase or decrease as the temperature is lowered, and that effect will be reversed if the temperature is raised. In short, the effect of temperature on α cannot be predicted for two solutes of different functionality. Hence for any given group of mixed solutes, α values are controlled primarily through experience and observations on the probability of interactions between given solutes and a given stationary phase.

The limitation on N and the resultant increased reliance on α made stationary phase selectivity of major import to the packed column, and has been largely responsible for the proliferation of some 300 different stationary phases for packed columns. Because much higher numbers of theoretical plates are attainable in open-tubular columns, solute separation factors – α – were initially less critical to the user of open-tubular columns. However, the inexorable increase in the demands placed upon the analytical chemist ultimately necessitated the development of high- N columns coated with high- α phases.

Low-Bleed Columns

As the column temperature is increased, there is an increase in the steady-state baseline signal. The chemical bonds of the stationary phase are under increased thermal stress, degradation fragments are produced at an increased but constant rate, and the baseline signal rises and remains steady as long as that temperature is maintained. In polysiloxane stationary phases, the degradation fragments consist largely of cyclic siloxanes, dominated by trimers and tetramers of (–Si–O–) to which the methyl (or other) substituents occupying the remaining two bonds of the tetravalent silicon atom may remain attached, or may cleave. True column bleed does not generate peaks or

humps; a signal that rises and then falls must have a ‘point source’. Bleed signal is annoying with any bleed-sensitive detector, and can be the limiting factor in GC-MS, especially with the newer ion trap mass spectrometers (ITD). For a given quality of stationary phase under a given set of conditions (temperature, carrier gas flow), bleed is always a function of the mass of stationary phase in the flow path. Hence, shorter, smaller diameter, thinner film columns will exhibit lower bleed levels than longer, larger diameter, thicker film columns.

At the present time, column bleed is usually reported in terms of pA of FID (flame ionization detector) signal at a given temperature, but this is an imprecise specification. It would be better to report bleed as ‘pg carbon emitted per unit time’ as measured on a *calibrated* detector. Only where the same detector is used under the same conditions for both determinations can different columns be truly compared in terms of ‘pA of FID signal’. Bleed signal from polysiloxane columns is generally attributed to cyclic siloxanes that usually arise from thermal and/or oxidative degradation of the phase, but contaminants in the detector or in gas lines supplying that unit, materials outgassing from septa and ferrules, and contaminating oils from column installation also contribute to what is *perceived* as column bleed. The latter sources are usually (but not always) dwarfed by the former, but their significance increases in the case of low bleed columns. It should also be noted that at elevated temperatures, even a pristine FID *without any column* generates 1–2 pA signal.

Some years prior to the invention of gas chromatography, Sveda, a Du Pont chemist working on bulk polymers, filed two patents on silarylene-siloxane polymers. Shown in **Figure 2** are generic structures of (A) the conventional 95% dimethyl–5% diphenylpolysiloxane (in which the phenyl groups are pendant to the siloxane chain), and (B) Sveda’s poly(tetramethyl-1,4-silphenylene siloxane).

Not surprisingly, the two forms display somewhat different selectivities toward solutes. More than 40 years after Sveda’s work, several column manufacturers began offering proprietary ‘low-bleed’ columns that would appear to be based on the silarylene siloxanes. The lengthy delay may have been partly due to the fact that, until quite recently, bleed rates from high quality ‘conventional’ columns were not considered excessive in most applications. A more probable cause is that silarylene polymers are not yet commercially available, so that those wishing to utilize them must resort to a sequential series of in-house syntheses that are both materials and labour intensive, each step of which is usually characterized by low yields.

Figure 2 Generic structures of (A) the conventional 95% dimethyl – 5% diphenylsiloxane and (B) Sveda's poly (tetramethyl-1,4-silphenylene siloxane).

Several pathways have been postulated for the thermal degradation of siloxanes, some of which require a proximity of two normally separated groups that would require folding of the siloxane chain. It has been suggested that such reactions might be blocked

by the insertion of groups that would make the chain more rigid and restrict its flexibility. Such efforts have led to the introduction, by more than one manufacturer, of stationary phases that are characterized by the generation of lower bleed signals, even at elevated temperatures, e.g. 360°C.

Figure 3 contrasts the bleed profiles of examples of 'first generation' (a silphenylene siloxane) and 'second generation' (a silphenylene siloxane containing 'chain-stiffening' groups) low-bleed columns. Note that the latter not only exhibits a bleed level about half that of the former, but the bleed pattern is simpler, making the phase especially valuable for those utilizing bleed-sensitive detectors such as the ion trap mass spectrometer. It also possesses a unique selectivity that has excited great interest among those interested in a variety of problematic separations, including the polychlorinated biphenyl congeners.

Column performance is also influenced by the deactivation, or surface preparation treatment. The observation that thin-film columns often exhibit adsorption toward active solutes, and that thicker films of stationary phase result in more inert columns,

Figure 3 Chromatograms of a column test mixture on 30 m × 0.25 mm, d_i 0.25 μm columns. Test mixtures were run at 130°C isothermal, and columns ramped to higher temperatures to determine bleed profiles. Note that the 'delta bleed' is 2.32 pA at 320°C for the 'second generation' column, versus 14.42 pA for the 'conventional' column. This is essentially the 'maximum temperature' of the latter column, which has reached a point where bleed increases exponentially with temperature. The latter column is capable of still higher temperatures, however, and exhibits a bleed signal of 5.47 pA at 340°C. Key: ---, first generation 35% diphenylpolysiloxane column; —, second generation 35% phenyl low-bleed column.

suggests that activity sometimes depends on whether solutes 'see' the surface. As solute molecules migrate through the stationary phase toward the siliceous surface, the carrier flow sweeps the solute molecules in the gas phase downstream. To re-establish the distribution constant in that portion of the column, solute molecules in the stationary phase reverse direction and migrate toward the mobile phase. Whether this impetus to change the direction of migration occurs before or after the solute has reached the surface would, under a given set of conditions, depend on the thickness of the stationary phase film.

The affinity of the surface for polar stationary phases is sometimes estimated by measuring the surface energy of the prepared surface. While both

the nature and strength of surface-to-polymer interactions are important to column performance, they are not necessarily predictable. A given 'high energy' surface is not always suitable for the deposition of a 'high energy' polymer. Architectural 'tailoring' of the surface can be as difficult as tailoring stationary-phase selectivity. The concept of 'coating efficiency', used in Figure 4, ($CE = 100 \times H_{\text{theor min}}/[H_{\text{observed}}]$) is often used to measure the compatibility of a surface for a given stationary phase.

Figure 4 shows four dimensionally identical columns under the same operational conditions and coated with the same experimental high phenyl stationary phase; each column received a different deactivation treatment. Note the third example (C),

Figure 4 Chromatograms of a test mixture on four dimensionally identical columns, all coated with the same experimental high phenyl stationary phase, but subjected to different deactivation pretreatments. Note the disappearance of 2-ethylhexanoic acid in (D) and the intercolumn variations in retention indices (I) for methyl naphthalene and undecanol. See text for discussion of the effects of the surface energies (γ) on coating efficiencies (CE). Solutes in order of elution: 1, 2-ethylhexanoic acid (totally adsorbed in chromatogram D); 2, 1,6-hexanediol; 3, 4-chlorophenol; 4, tridecane; 5, 2-methylnaphthalene; 6, 1-undecanol; 7, tetradecane; and 8, dicyclohexylamine.

which has high surface energy but very poor coating efficiency. (A), (B) and (D) all are nonbeaded surfaces, but the coating efficiencies of (A) and (B) are significantly better than that of (D). The coating efficiencies of these three columns vary in the order $2 > 1 > 4$, while the surface energies vary in the order $1 > 4 > 2$. The column with the lowest surface energy of the coatable surfaces (column B), yields the highest coating efficiency. In column (D), the acid peak disappeared. In every case, there is almost surely at least a slight effect on selectivity. One of our better ways for estimating this quality is the duplicability of retention indices for polar and apolar compounds, and column-to-column variations in these comparisons imply that closely eluting solutes of different functionalities may exhibit a given elution order on the one column, and a different elution order on the other column. These data indicate that both the stationary phase (which may be proprietary) and column pretreatments (which are almost always proprietary and vary from manufacturer to manufacturer) affect retention factors, separation factors, and even the elution order. Surface pretreatments, including but not limited to deactivation, can, and often do, exert profound effects on overall column performance.

Conclusions

During its half century history, gas chromatography (GC) has evolved to become the world's most widely used analytical technique. The growth has accelerated with the commercial availability of columns, the quality of which has shown consistent improvements, and by the continuing development of compatible instrumentation and combined techniques (e.g. gas chromatography-spectrometry, GC-AED, etc.). Also important to that growth is the fact that the technique possesses separation powers so great that the unskilled analyst can abuse the technique and still generate useful data. Other analytical methods (e.g. capillary electrophoresis, capillary zone electrophoresis, liquid chromatography) have shown promise of greatly increased growth, but GC has not stagnated. Many of the elements necessary for 'fast' GC have been known for some time, but their application usually requires instrumental modification and adaptation beyond the purview of most practising analysts. Some cracks in this barrier have recently appeared. Developments in more selective stationary phases, electronic pneumatic controls, micropacked columns, and shorter columns of smaller diameter now permit some users to demonstrate improved separations while reducing analysis times. Appreciable time savings have been demonstrated merely through refinement of operational parameters (temperature,

program rates, gas velocity). By changing both operational and design parameters (e.g. column dimensions), analysis times using unmodified instrumentation have been reduced from 30 min to a few seconds. A greater utilization of these newer developments, however, will require honing the skills of the average analyst through continuing education.

Glossary

Based on the most recent recommendations of the International Union of Pure and Applied Chemistry (IUPAC), which appeared in *Pure and Applied Chemistry* 65: 819-872 (1993).

A Eddy diffusion, or packing factor term of the van Deemter (packed column) equation.

α Separation factor; the adjusted retention time of the more retained solute relative to that of the less retained solute.

- B** Longitudinal diffusion term of the van Deemter and Golay equations.
- β** Column phase ratio. The column volume occupied by mobile (gas) phase relative to the volume occupied by stationary phase. In open-tubular columns: $\beta = [r_c - 2d_f]/[2d_f] \cong r_c/2d_f$.
- c_M, c_S** Solute concentrations in mobile and stationary phases, respectively.
- C** Resistance to mass transfer (or mass transfer) in the van Deemter (or Golay) equations; C_M and C_S denote mass transfer from mobile to stationary and from stationary to mobile phases, respectively.
- d_c** Inner diameter of the column. Both mm and μm are commonly used. The latter, while consistent with the units used for d_f , implies three significant figures, which is rarely true.
- d_f** Thickness of the stationary phase film, usually in μm .
- D** Diffusivity; D_M and D_S denote solute diffusivities in the mobile and stationary phases, respectively; usually given in $\text{cm}^2 \text{s}^{-1}$.
- F** Volumetric flow of the mobile phase, usually in $\text{cm}^3 \text{min}^{-1}$. Many practical chromatographers assume equivalency with (and hence employ) mL min^{-1} .
- FID** Flame ionization detector.
- GC-MS** The combination of gas chromatography and mass spectrometry, usually a single integrated unit in which fractions separated by GC are sequentially introduced to the MS.
- H** Length equivalent to one theoretical plate (height equivalent to a theoretical plate): $H = L/N$. When measured at u_{opt} , the result is termed H_{min} .
- k** Solute retention factor (formerly partition ratio). Ratio of the amounts of a solute (or time spent) in stationary and mobile phases, respectively. Because all solutes spend t_M time in the mobile phase, $k = [t_R - t_M]/t_M$, and $k = t'_R/t_M$.
- K_c** Distribution constant. Formerly K_D . Ratio of solute concentrations in stationary and mobile phases, respectively: $K_c = c_S/c_M$.
- L** Length of the column, usually expressed in metres for column length, in cm for the determination of \bar{u} , and in mm for the determination of H .
- N** Theoretical plate number; $N = [t_R/\sigma]^2$, where σ is the standard deviation of the peak.
- N_{req}** Number of theoretical plates required to separate two solutes of a given alpha and given retention factors to a given degree of resolution: $N_{\text{req}} = 16R_s^2[(k+1)/k]^2[\alpha/(\alpha-1)]^2$.
- o.d.** Outer diameter of the column.
- r_c** Inside radius of the column.
- R_s** Peak resolution. A measure of separation as evidenced by both the distance between the peak maxima and by the peak widths. ASTM and IUPAC definitions are based on w_b (peak width at base) measurements, which require extrapolation. If peaks are assumed to be Gaussian, then $R_s = 1.18[t_{R(B)} - t_{R(A)}]/[w_{h(A)} + w_{h(B)}]$.
- σ** Standard deviation of a Gaussian peak.
- t_M** Gas hold-up time. The time (or distance) required for a nonretained substance (e.g. mobile phase) to transit the column.
- t_R** Retention time. The time (or distance) from the point of injection to the peak maximum.
- t'_R** Adjusted retention time. Equivalent to the residence time in stationary phase; difference of the solute retention time and the gas hold-up time: $t'_R = t_R - t_M$.
- \bar{u}** Average linear velocity of the mobile (gas) phase: $\bar{u} (\text{cm s}^{-1}) = L (\text{cm})/t (\text{s})$.
- V** Volume. V_M and V_S represent volumes of the mobile and stationary phases, respectively.
- w_b** Peak width at base. Determined by measuring the length of baseline defined by intercepts extrapolated from the points of inflection of the peak, and equivalent to four standard deviations in a Gaussian peak.
- w_h** Peak width at half-height. Measured across the peak halfway between baseline and peak maximum, this can be measured directly without extrapolation, and is equal to 2.35 standard deviations in a Gaussian peak.

Derivatization

Introduction

Gas chromatography (GC), the longest established instrumental chromatographic technique, dominated

the separation field from the early 1950s until the mid-1970s when high performance liquid chromatography (HPLC) became a competitive technique. During this 20-year period, considerable effort was expended in developing procedures to make compounds sufficiently volatile, more thermally stable and less polar so that they would be more amenable to GC analysis. Such efforts were aimed almost

exclusively at removal of active hydrogen atoms(s) from protonic functional groups by the action of a suitable reagent, giving rise to a derivative with the hydrogen atoms substituted by less active functional groups.

Development of a particular derivatization method requires a good knowledge of organic chemistry, taking into consideration as many reaction mechanisms as possible. This is particularly true for the derivatization of protein amino acids, where so many different chemical groups are involved, such that a remark has been made about having here 'the whole of Beilstein'. The history of their more or less successful derivatization can be found in the book *Amino Acid Analysis by Gas Chromatography* (see Further Reading).

In general, the nature of the compounds to be analysed and their chemical properties govern the choice of the particular chemical treatment. This does not mean, however, that the reactions used on a macro-scale by organic chemists can be automatically adopted to the scale of microlitre volumes. The recent discovery of chloroformate-induced esterification of carboxylic acids is a good example of this. Over time, many derivatization methods have become more or less obsolete as their original usefulness was determined by a lack of alternative methods for the determination of minute amounts of some analytes, especially those in biological fluids. Until the discovery of immunoassay (radioimmunoassay, RIA, and enzyme immunoassay, EIA) and the development of specific and sensitive HPLC detectors, the electron-capture detector (ECD) in GC was the only way to reach picomole concentration levels. At that time, therefore, there was considerable interest in the conversion of analytes into perhalogenated products with a correspondingly high ECD response. Some of these methods or principles still persist; others do not. A comprehensive list of various chemical treatments can be found in the *Handbook of Derivatives for Chromatography* by Blau and Halket (see Further Reading). Some of the older useful methods and recent novel discoveries will be discussed in more detail below (see also the reviews by Hušek and Wells listed in the Further Reading section).

Esterification

Carboxylic acid groups usually require treatment with a group-oriented reagent that will not react in most cases with any other protonic groups that may be present. The choice of treatment depends on what class of acidic compounds – with or without extra reactive groups in the molecule – is to be esterified and what kind of detection (ECD or flame ionization detection, FID) is required.

Esterification with Acidified Alcohols

For analytical work, esterification with methanol through to isoamyl alcohol is best done in the presence of a volatile catalyst such as hydrogen chloride, thionyl chloride or acetyl chloride, which can be readily removed together with any excess alcohol. Fatty acids are often methylated by a short boiling with BF_3 /methanol, and this catalyst has proved to be effective even for transesterification of acylglycerols (neutral lipids are, however, most easily saponified using sodium or potassium hydroxide in methanol). Higher alcohols, most often *n*-butanol and isobutanol, have been used for HCl-catalysed esterification of amino acids in two steps (with lower alcohols, evaporative losses of the lower mass members occur). For effective conversion, heating at or above 100°C is required.

Esterification via Pyrolytic Methylation

Strongly basic quaternary salts of ammonia, e.g. tetramethyl or trimethylphenylammonium hydroxide in methanol, when co-injected with fatty acids into the heated inlet of a GC, convert the acids into quaternary salts that are immediately pyrolysed into methyl esters and swept onto the analytical column. However, this rapid procedure is not recommended for polyunsaturated fatty acids because isomerization of the double bonds may occur owing to the high inlet temperature and alkalinity of the reagents. It has been reported that tetraalkylammonium fluorides, cyanides or acetates frequently offer considerable advantages over the hydroxides in terms of derivatization selectivity without compromising derivatization efficiency. Regarding on-column benzylation reagents, the 3,5-bis(trifluoromethyl)benzyltrimethylphenylammonium fluoride and some related compounds have been shown to be very useful new derivatization reagents with a variety of uses (see the review by Wells in the Further Reading section). Dimethylformamide dimethylacetal ($(\text{CH}_3)_2\text{NCH}(\text{OCH}_3)_2$) and its higher alkyl analogues have also been employed as hot inlet esterification agents. Hopes of being able to use them for one-step derivatization of amino acids have not been fulfilled, however.

Esterification with Diazoalkanes

Diazomethane, a yellow gas normally used as a solution in ether, readily esterifies fatty acids in the presence of methanol at room temperature and excess reagent can easily be removed by evaporation. However, the gas is highly carcinogenic and unstable, partially reacting with double bonds, carbonyl, phenolic and hydroxyl groups. This method, once popular, is now the exception. The same is true for the

higher analogues diazoethane and phenyldiazomethane (used to make benzyl esters). The recent use of commercially available trimethylsilyldiazomethane (solution in hexane) has proved to be useful in some applications.

Esterification via Carbodiimide-Induced Coupling

The carbodiimide-coupled esterification of carboxylic acids is a well-known reaction in organic chemistry. *N,N'*-Dialkylcarbodiimides act as water scavengers, promoting condensation of an acid with an alcohol while being transformed into an *N,N'*-dialkylurea (from $X-N=C=N-X$ to $X-NHCONH-X$, where X is an alkyl radical). For example, diisopropylcarbodiimide (DIC) was used for the esterification of some aromatic acids with hexafluoroisopropanol. A concentration of 0.1–0.15% DIC and the alcohol in hexane was found to be sufficient to esterify within 1 min.

Esterification with Alkyl Halides

Alkyl (aryl) iodides, bromides (less often chlorides) have been used for treatment of potassium, *t*-amines, tetraalkylammonium or 'crown' ether salts of acids in a suitable organic solvent such as acetonitrile, acetone or methanol. Corresponding alkyl/aryl esters are formed without heating the sample at optimum conditions in high yields. It has been reported by Wells and co-workers (see Further Reading) that macroporous quaternary ammonium anion exchange resins are a very effective support matrix for the methylation of strongly acidic organic analytes with methyl iodide in either supercritical carbon dioxide or acetonitrile. The isolation and determination of simple volatile aliphatic acids from urine by trapping on ion exchange resin followed by simultaneous derivatization with pentafluorobenzyl bromide (PFBBBr) and extraction with supercritical carbon dioxide has also been reported. The electron-capturing pentafluorobenzyl (PFB) esters have become increasingly popular for GC-ECD analysis of fatty acids regardless of chain length. Conversion to PFB esters has been reported to succeed in the presence of acetonitrile and diisopropylethylamine in 10 min.

Silylation

A wide range of highly reactive and specific reagents for nearly every application with a trimethylsilyl (TMS) or the increasingly popular *t*-butyldimethylsilyl (TBDMS) donor is now available. These reagents, which are of general utility, will be discussed in a separate section. Some of them can convert the carboxylic acid group into the TMS ester ($RCOO-Si(CH_3)_3$) practically instantaneously and

GC analysis can be done by direct injection of the reaction mixture. Reagents with a TBDMS donor require longer reaction times but provide hydrolytically more stable derivatives. Under controlled conditions, with mild silylating agents, e.g. hexamethyl disilazane (HMDS), only the carboxylic acid group will be esterified. Silylation is the preferred way for treating dicarboxylic acids or polycarboxylic compounds. Haloalkylsilylation reagents have been used for sensitive ECD detection but they are expensive and less popular than they once were.

Derivatization by Alcoholysis of the Intermediate Mixed Anhydrides

Haloalkyl anhydrides, especially the perfluorinated ones of acetic, propionic and butyric acids, are able to promote condensation reactions with an alcohol (see Table 1 for the reagents and abbreviations), when in a molar excess over the alcohol. TCE, TFE or HFIP in combination with TFA or HFBA have often been used to attain higher ECD response. Heating is usually employed without the catalytic presence of an organic base. This approach will be mentioned again in the next section.

At the beginning of the 1990s, chloroformates with the simplest alkyl groups, i.e. methyl and ethyl chloroformate (MCF and ECF), were shown to act as exceptionally rapid esterification reagents. The catalytic presence of pyridine has been found to be a prerequisite for ester formation; water can be, or for some applications should be, a constituent of the medium, together with an alcohol and commonly acetonitrile also. This promising treatment has a broader utility and will be discussed further. The reaction mechanism is based, as in the first case, on alcoholysis of a mixed anhydride intermediate. The advantageous use of this approach in comparison with the former can be seen from Table 2.

Acylation/Alkylation

Reagents treated in this section have proved to be especially suitable for handling the various nitrogen protic groups for which silylation with TMS donors is clearly inferior due to the lability of the N–Si bond. A comprehensive review on the derivatization of amines for GC analysis has been published by Kataoka (see Further Reading).

The perfluorinated anhydrides, despite their much higher molecular weight, yield derivatives of high volatility since interaction between the perfluoroalkane chain and a nonfluorinated stationary phase is substantially weakened. The retention of perfluoroalkyl(acyl) derivatives is, therefore, often markedly less

Table 1 Electrophoric reagents frequently used for esterification, acylation and alkylation

Haloalkyl(acyl) group	Matrix	Formula	b.p. (°C)	Abbreviation
2-Chloro-	Ethanol	$\text{ClCH}_2\text{CH}_2\text{OH}$	129	2CE
2,2,2-Trichloro-	Ethanol	$\text{CCl}_3\text{CH}_2\text{OH}$	151	TCE
	Ethyl chloroformate	$\text{CCl}_3\text{CH}_2\text{OCOCl}$	171	TCECF
2,2,2-Trifluoro-	Ethanol	$\text{CF}_3\text{CH}_2\text{OH}$	78	TFE
	Acetic anhydride	$(\text{CF}_3\text{CO})_2\text{O}$	40	TFAA
Chlorodifluoro-	Acetic anhydride	$(\text{CF}_2\text{ClCO})_2\text{O}$	96	CDFAA
1,1,1,3,3,3-Hexafluoro-	Isopropanol	$(\text{CF}_3)_2\text{CHOH}$	59	HFIP
2,2,3,3,3-Pentafluoro-	Propanol	$\text{C}_2\text{F}_5\text{CH}_2\text{OH}$	81	PFP
	Propionic anhydride	$(\text{C}_2\text{F}_5\text{CO})_2\text{O}$	96	PFPA
2,2,3,3,4,4,4-Heptafluoro-	Butanol	$\text{C}_3\text{F}_7\text{CH}_2\text{OH}$	96	HFB
	Butyric anhydride	$(\text{C}_3\text{F}_7\text{CO})_2\text{O}$	108	HFBA
	Butyryl chloride	$\text{C}_3\text{F}_7\text{COCl}$	39	HFB-Cl
Pentafluorobenzoyl	Chloride	$\text{C}_6\text{F}_5\text{CH}_2\text{COCl}$	158	PFB-Cl
Pentafluorobenzyl	Bromide	$\text{C}_6\text{F}_5\text{CH}_2\text{Br}$	174	PFBBr
	Chloroformate	$\text{C}_6\text{F}_5\text{CH}_2\text{OCOCl}$		PFB-Cl
	Hydroxylamine	$\text{C}_6\text{F}_5\text{CH}_2\text{ONH}_2$		PFBHA
	Aldehyde	$\text{C}_6\text{F}_5\text{CHO}$	165	PFBA

than that of their hydrocarbon analogues. Another reason for their popularity is the high sensitivity to ECD, which increases rapidly with increase in F substitution. The response can be further augmented by incorporation of Cl, Br or I atoms into the molecule but the volatility of such derivatives declines rapidly and reagents carrying more than three Cl atoms are unsuitable for derivatization of higher mass analytes.

Treatment of Amino and/or Hydroxyl Groups

Reactive anhydrides listed in Table 1 are frequently employed for this purpose. Acetic anhydride, which has the additional advantage of reacting in aqueous media, has proved its usefulness for esterification of phenolic hydroxyl groups. However, its lower reactivity and the lower volatility of the (per)acetylated forms prevents its wider use.

Acylation of amino acid butyl or isobutyl esters with TFA or HFBA carried out at 100°C or more, usually in the presence of a solvent such as dichloromethane after evaporation of the first esterification

medium, is one of the best-established procedures of the 1960s and 1970s. All protein amino acids, including arginine, which is the most difficult amino acid to derivatize and determine by GC, have been successfully analysed and quantitated. Experience gained in the derivatization of amines, alcohols and acids is valuable for procedures for amino acids. A study of these approaches affords a basic knowledge of commonly occurring derivatization problems.

Acid halides have been employed for acylation less often. Except for PFB-Cl, which has even been used for acylation of amino acid isobutyl esters, the use of other acid chlorides is rather rare. However, surprisingly good results have been reported for catecholamines treated with HFB-Cl, which results in ready acylation of the phenolic, amino and alcoholic groups of analytes in an aqueous buffer. Unlike other chlorides, which are almost explosively reactive with water, HFB-Cl appears to be more stable towards hydrolysis. Many applications, aimed at the trace analysis of amines, phenols and alcohols with ECD by acylation with haloanhydrides are outside the

Table 2 Comparison of the reaction conditions for HFBA- and the ECF-induced esterification of carboxylic acids

	HFBA-catalysed ^a		ECF-catalysed ^b	
Medium	Chloroform		Chloroform	Water-acetonitrile (1 : 1)
Alcohol	TCE (1–10%)	EtOH (20%)	EtOH (1%)	EtOH (30%)
Reagent	HFBA (six-fold volume)		ECF (1%)	ECF (5%)
Base	None	Pyridine (25%)	Pyridine (2%)	Pyridine (8%)
Reaction time	30 min	4 min (boiling)	Few seconds	
Yield	Not given		> 90%	
Extraction	Chloroform versus aq. HCl and NaOH		Hexane versus aq. NaHCO ₃

scope of this article; for details the reader should consult the Blau and Halket book or the papers by Poole (see Further Reading).

The amino group is best derivatized in aqueous media with chloroformates. Catecholamines are treated with MCF; if the alcoholic OH group is present it is silylated or acetylated in addition. During this step the MCF-alkylated phenolic hydroxyls reconvert to O-TMS or O-acetyl esters and only the amino group retains the alkyl group from the MCF. On well-deactivated capillaries the analysis succeeds even without this extra treatment. When tertiary amines are treated with chloroformates, the smallest alkyl group attached to the nitrogen undergoes a displacement and the amine is thus transformed to a carbamate. Hydrolysis of the latter yields a secondary amine, which is then exposed for further derivatization.

Concurrent Treatment Involving Carboxylic Groups

As already mentioned, the perfluorinated anhydrides TFAA, HFBA and less often the more expensive PFPA, can promote esterification of carboxylic groups provided that they are in a molar excess over the haloalcohol present. It is logical to suppose that even polyfunctional acids might be effectively treated, since side chain groups are acylated smoothly. This has been confirmed experimentally by treating hydroxyphenolic acids, bile acids and even amino acids, the carboxylic and side chain groups of which are esterified and acylated simultaneously. It is assumed that the reaction proceeds in two steps, i.e. by the formation of mixed anhydride intermediate that is subsequently alcoholysed to the ester, as shown by *p*-hydroxyphenylacetic acid treated with PFPA/HFIP (reaction [I]). Derivatization of a number of carboxylic acids has been achieved by treatment with TFAA and HFB or TFE in the presence of an organic base with heating to 60°C for 30–40 min.

Alkylation Preceding the Carboxyl Treatment

This procedure deals with amino acids in the reverse order – first the amino group, including any side chains, is derivatized, and then the carboxyl group is methylated or silylated. The unique ability of chloroformates to react rapidly with analytes in aqueous media is utilized in a procedure employing isobutyl chloroformate (IBCF) followed by methylation with diazomethane. More than 50 amino acids (with the exception of arginine) have been analysed in this way as their *N*-isobutyloxycarbonyl (IBOC) methyl esters.

Alternatively, instead of methylation, the carboxylic group can be treated with a TBDMS donor and many amino acids have been analysed as *N*(O,S)-IBOC TBDMS esters. An ECD-oriented procedure was based on derivatization of the amino groups with dimethylchlorothiophosphate, followed by methylation (reaction [II]).

Likewise a three-stage treatment involving acylation of the amino groups with HFBA, extractive alkylation with PFBBR (for the carboxyl groups) followed by BSTFA silylation of aliphatic hydroxyl groups served the same purpose. The derivatization of threonine is an example of this procedure (reaction [III]). This scheme may seem unnecessarily complicated but the treatment is rapid and conditions are mild as each group undergoes its respective derivatization. In general the use of one reagent to react with different groups requires more drastic conditions.

Oximation of keto groups is one way to prevent isomerization (and/or enol formation) of keto acids before further derivatization by, for example, silylation. The keto group reacts with hydroxyl, methoxy

or ethoxyamine as follows:

If one wishes to shift the derivatization products of simple aliphatic keto acids to products with greater retention times, then a correspondingly higher boiling reagent PFBHA (see Table 1) can be employed.

Cyclization

Some reagents selectively react with two protonic groups to form a heterocyclic compound with five, six or seven atoms, i.e. the groups to be treated are in positions 1,2, 1,3 or 1,4 on an aliphatic chain or 1,2 on an aromatic ring (see the review by Poole and Zlatkis listed in the Further Reading).

Acetals/ketals

This kind of cyclization is often used to provide protection for *cis*-diols and thiols. It is based on the reaction of aldehydes or ketones with 1,2-diols in the presence of an acid catalyst and proceeds via the formation of a hemiketal that is further rearranged to the dioxolane product (called acetonide or isopropylidene when acetone is used as the ketone; see reaction [V]).

Acetonide derivatives are prepared, e.g. from α -monoacylglycerols (β -isomers do not react), and separated by GC. Corticosteroids with *cis*-C-20,21- or C-17,20-dihydroxy groups form acetonides under mild conditions and the products are suitable for GC analysis. The acetonide group is also stable under conditions of further treatment such as silylation or acetylation. The reaction is specific to *cis*-diols since the *trans*-C-20,21 diol does not form an acetonide. Siliconides are also formed by a similar mechanism when dimethylchlorosilane is used in pyridine, but multiproduct formation and instability of the derivatives has prevented wider use.

Boronates

Many diols are best handled with boronic acids. Alkyl boronates were used extensively in the 1970s

since they exhibit a broad ability to cyclize and are able to bridge diols up to a 1,4 position. The cyclic products (reaction [VI]) are stable enough to be analysed by GC and may even be made in the GC inlet.

However, hydrolytic stability is not good and the products of reaction with a single OH group cannot be analysed. This can cause problems with, for example, steroids containing an additional alcohol group or groups next to the diol. The required additional treatment (acetylation, silylation) often results in unwanted by-products. Various alkyl groups, such as *t*-butyl, have been investigated with a view to improving the stability of the product, but the results have not always been as expected. The *n*-butaneboronates offer a convenient compromise between volatility and stability. For ECD, 2,4-dichloro- and 3,5-bis(trifluoromethyl)benzeneboronic acid have proved to be the best, since PFB-boronates are unstable to hydrolysis. Some useful applications include treatment of monosaccharides with benzeneboronic acid in acetone to give mixed acetonide-boronate products, as shown in reaction [VII]).

The action of methaneboronate on the corticosteroid (structure [VIII]) leads to an interesting rearrangement in the side chain and the selective reaction of the *cis*-diol group of prostaglandin F allows it to be distinguished (after silylation) from the structure with a *trans*-diol group, which does not react (structure [IX]). Boronates as reagents for GC analysis

are now rather ancient history but they do represent a considerable amount of successful past effort.

Oxazolidones

The conditions for the condensation of amino acids with 1,3-dichlorotetrafluoroacetone (DCTFA) were established in the early 1980s, but before the method could establish its worth HPLC became the preferred technique and the reagent disappeared from the catalogues of all the major suppliers.

Substitution of halogens into the acetone molecule enhances the acidic character of the carbonyl group and promotes formation of stable adducts that are not otherwise obtained with aliphatic ketones. A scheme for some reactions with DCTFA is shown in scheme [X].

The double-step treatment with DCTFA followed by HFBA in the same aprotic medium, together with the subsequent analysis by capillary GC, gave the most rapid analysis of the protein amino acids, including arginine, at the time the method was developed. With an ECD, femtomole levels are easily attained. The method was originally developed for the derivatization of thyroid hormones with three to four iodine atoms in the molecule. The derivatized

thyroxine T_4 , with a molecular mass of over 1000 Da, is one of the largest compounds ever analysed by GC, the haloalkyl moiety providing relatively high volatility and high electron-capture response. However, the method came at a time when immunoassay was developed as an alternative and further applications of this derivatization method have not been pursued.

The potential of DCTFA to act as a reagent for detector-oriented derivatization has not been fully explored. As shown in the scheme in Figure 4, application to various classes of carboxylic acids still remain to be exploited.

Phosgene, dissolved in toluene or liberated from trichloromethyl (TCM) chloroformate or bis(TMC) carbonate, is able to cyclize adjacent groups of amino alcohols, aromatic diols, etc., as shown for catecholamines. The cyclic carbonate is not sufficiently stable and must be transformed to, for example, a TMS ester (reaction [XI]). Phosgene-induced cyclization to oxazolidones has been used for the GC analysis of enantiomers of pharmaceutically important amino alcohols. More details of the use of this reagent can be found in the review by Gyllenhaal and Vessman (see Further Reading).

Pyrimidines

Of the selective procedures for bifunctional compounds that result in cyclized products, the last to be described is that in which pyrimidines are formed by the action of acetylacetone or hexafluoroacetylacetone, or even malonaldehyde, on the guanidino group (reaction [XII]). This could represent a solution for the pre-treatment of arginine but the procedure is time-consuming and requires heating. For further information, see the review by Poole and Zlatkis listed in the Further Reading section.

Peralkylation

In addition to amino acid mixtures, another difficult class of compounds to deal with is the acidic metabolites of physiological fluids. Even when compounds with amino groups are not present (except in the case of glycine conjugates), the various classes of acids present – mono-, di- and tricarboxylic acids, keto and hydroxycarboxylic acids, aromatic acids with substituted chains, etc. – make sample preparation particularly challenging. There are one-step, one-reagent procedures that are able to derivatize most protic groups in such a mixture of analytes. These can be effective with alkylating or silylating reagents and also with chloroformates, under the active participation of a component in the reaction medium.

Alkylating Agents

Isopropyl bromide has proved to be a useful reagent for amino acids dissolved in dimethylsulfoxide/sodium hydride, except for the determination of arginine. Methylation of acids with diazomethane has also been used for metabolic profiling despite the formation of artefacts. Resin-mediated methylation of polyfunctional acids found in fruit juices has also proved successful. Fumaric, succinic, malic, tartaric, isocitric and citric acids, isolated from fruit juices by trapping onto anionic ion exchange resins, can be efficiently converted to methyl esters by reaction with methyl iodide in both supercritical carbon dioxide and acetonitrile. To provide for the analysis of even short chain fatty acids in serum, a procedure has been developed with benzyl bromide. This has been successfully employed for serum and urine organic acid profiling. The method cannot be used for citric acid or sugar-related acids.

Silylating Agents

Silylation is the most widely used method for metabolic profiling, especially for urinary organic acids. On the other hand its use for amino acids has a number of disadvantages as already mentioned. For some applications, silylating agents are too powerful in that they are able to react with compounds which will not elute from the column. The most popular reagents are listed in Table 3 and many others are described in detail in the Fluka handbook edited by van Look (see Further Reading). For metabolic profiling the TMS donors are used much more frequently than the TBDMS donors although the latter are more convenient for treating amino groups in those applications where greater hydrolytic stability is required. Reactivity of functional groups towards silylation is as follows: alcohols > phenols > acids > amines > amides. Disadvantages include the need to operate under

Table 3 Reagents for silylation: (I) most common TMS donors; (II) a TBDMS donor; and (III, IV) reagents for special application**(I) Trimethylchlorosilane (TMCS)**

First silylation reagent prepared (1944)
Rarely used in analytical applications alone,
rather in mixtures with HMDS and pyridine

***N,O*-Bis(TMS)acetamide (BSA)**

First reported in 1963
as a more potent TMS
donor;
usually in combination
with TMCS (1–20%)

TMSimidazole (TMSIM)

Prepared in 1965;
considered to be the
strongest reagent
available for silylation
of hydroxyl groups

**(II) *N*-Methyl-*N*-*t*-butyldimethylsilyl-
trifluoroacetamide (MTBSTFA)**

Alternative silyl

for simultaneous oximation & silylation at room temperature (reported 1986) as follows:

anhydrous conditions, to heat the sample and to inject a reactive mixture onto the column. This means that the compounds of interest have to be isolated, the extraction medium evaporated and the column replaced more frequently. For further information on profiling see the review by Sweetman.

Chloroformates

Chloroformates are known in organic chemistry for their ease of coupling to acids, resulting in the forma-

tion of so-called mixed anhydrides:

which are, in most cases, stable enough for GC analysis and potentially even reactive enough with amino acids to give peptides. Coupling with an acid is mostly successful in an organic solvent and in the presence of a strong base such as triethylamine (TEA). Considerable effort has been expended into finding reaction conditions to accelerate decarboxylation of the

mixed anhydride to the ester but with the exception of 2-keto acids the process was far from smooth. However, it was found fortuitously that on a micro-scale the presence of pyridine in a mixture with acetonitrile or water and alcohol results in immediate esterification. The alkyl chloroformates previously used for treating amines and phenols only suddenly became the general-purpose reagent.

The reaction mechanism is based on alcoholysis of the intermediate alkoxycarbonyl ester (the mixed anhydride). On the numerous applications published since 1990, the results for amino acids are especially impressive. It has been found that the alkyl group of the reagent and the alcohol need not be the same and different combinations lead to a variety of esters. In the field of metabolic profiling there is a report on simultaneous analysis of amino acids with other classes of compounds in serum without the need to isolate the analytes from the matrix. Profiling of urinary organic acids, for example, has been made possible after a simple sample pretreatment. Details are given in the review by Hušek (see Further Reading).

Conclusion

Silylating reagents were introduced in the 1960s and have been widely accepted as general purpose derivatizing reagents for GC, especially for polyfunctional compounds where derivatization is reduced to a one-step process. In the 1990s chloroformates were discovered as another family of powerful reagents which, in conjunction with a component of the medium, readily enable derivatization of many hydrogen-containing groups. They bring the additional advantage of derivatization in aqueous media, which often considerably simplifies the sample work-up. Last but not least, advanced alkylation/esterification procedures allow the simultaneous derivatization and extraction of analytes in sample matrices. The present

emphasis and future advances will focus on simplification and speed-up of sample preparation methods by process automation and combination of derivatization with work-up procedures.

Detectors: General (Flame Ionization Detectors and Thermal Conductivity Detectors)

D. McMinn, Gonzaga University, Spokane, WA, USA

Copyright © 2000 Academic Press

The two most common detectors for use after separation by gas chromatography (GC) are the flame ionization detector (FID) and the thermal conductivity detector (TCD). They are considered general (non-selective) detectors since they respond to virtually all

components that they encounter. In a strict sense of course this is not true, especially for the FID which does not respond to fixed gases or to gases commonly used as carrier gases. None the less, it is responsive to most components of interest and is clearly not selective in comparison to an electron-capture or nitrogen-phosphorus detector.

It is sometimes useful to denote detectors as ionizing or nonionizing depending on their mode of

action. By their very nature, ionizing detectors are destructive and the sample is not available for additional analysis. On the other hand, nonionizing detectors do not destroy the sample. Thus, two detectors may be set up in series, with the sample first encountering the nonionizing detector, and then directed to the ionizing detector. Of all the detectors available for use following separation by GC, the FID and the TCD are the leading examples of each of these types. These general-purpose detectors are in wide use following both packed column and capillary separations.

The material which follows is directed mainly to applications after capillary column separation, although some reference to packed columns is necessary in order to complete the discussion. Further details regarding packed column applications can be found by consulting the Further Reading section.

The Flame Ionization Detector

The FID was developed in 1958 by McWilliam and Dewar in Australia and almost simultaneously by Harley, Nell and Pretorius in South Africa and quickly became the detector of choice in commercial instrumentation. As an ionization detector, the FID responds readily to compounds that contain carbon and hydrogen and to a lesser extent to some compounds containing only carbon. It is unresponsive to water, air and most carrier gases. Because of its broad applicability and relative ease of operation, it is probably the most common detector in GC systems. The FID responds quickly and can be constructed with a small internal volume, which makes it especially well suited for capillary GC.

Response of an FID is due to the sample being burned in a fuel-rich mixture and producing ions. In the same process, electrons are produced. Either ions or electrons are collected at an electrode and produce a small current. Since there are virtually no ions present in the absence of sample, the baseline is stable and the current is easily converted to a voltage and amplified to produce a signal. The response to most hydrocarbons is about 0.015 C g^{-1} carbon.

As shown in **Figure 1**, the most often used configuration has the jet tip at approximately 200 V relative to the collecting electrode. For use with capillary columns, a smaller jet tip (c. 0.3 mm i.d. rather than the 0.5 mm used with packed column configurations) is utilized in order to increase detector sensitivity. The capillary column is usually inserted through the ferrule and then a few centimetres are broken off and discarded. Ideally, the column is positioned within 1–2 mm of the jet tip and column effluent enters the detector and mixes with hydrogen (fuel) and make-up gas without undue contact with metal surfaces. This

Figure 1 Cross-sectional diagram of a flame ionization detector.

mixture is combusted in an excess of air and the organic components are decomposed into ions. The ion chemistry of the diffusion flame has been studied by mass spectrometry. It appears that the ultimate positive charge carrier is H_3O^+ (or clusters of this with water molecules) resulting from charge transfer reactions from the initially formed ions (principally CHO^+). Thus the detector is often referred to as providing an 'equal per carbon response'.

This response to hydrocarbons allows one to quantify mixtures, for example from petroleum samples, without necessarily identifying each of the components individually present. With compounds other than hydrocarbons, the response is decreased when partially oxidized carbon atoms are present. This requires corrections to be made when the compounds contain, for example, oxygen, nitrogen or halogens. Either pure sample compounds or compounds of similar structure are used to establish appropriate response factors. Alternatively, the concept of effective carbon number has been updated to provide a model for the quantification of components in a complex organic mixture if they can be assigned to general functional group categories.

When used with narrow capillary columns, the FID usually requires a make-up gas for maximum sensitivity. The wider (530 μm) columns can be operated at

a higher carrier gas flow rate and may often be used without the additional make-up gas. For most operations the total flow rate (column + make-up) will be 20–60 mL min⁻¹. The fuel and air flow rates are maintained close to that recommended by the manufacturer – often 30–40 mL min⁻¹ for the hydrogen fuel and about 10-fold higher for the air. Under these conditions, the minimum detectable amount (MDA) of organic compounds is approximately 10–100 pg, depending on the structure. In addition, response is usually linear from the MDA to a concentration some 10⁷ times as great. (This higher limit is often beyond the loading capacity of narrow-bore capillary columns.) Flows to the detector can be adjusted while using standard samples containing the components of interest in order to obtain maximum response.

Water is a product of the combustion process producing the ions. Thus, the detector assembly must be kept hot in order to prevent condensation. A convenient guide is to have the detector 20–50° greater than the upper column temperature, but in no case lower than 150°C. Then water vapour, along with the other combustion gases, is swept out of the detector body. With most instruments, once the thermal environment of the detector has stabilized, temperature fluctuations are small and easily tolerated.

The FID is often described as a ‘forgiving’ detector since acceptable results are obtained even when the gas flows and other conditions are not optimized. None the less, some caution must be taken to avoid baseline drift, loss of sensitivity and the presence of spurious peaks. It is important to ensure that the gases employed are free from hydrocarbon impurities. Filters are available for this purpose. The flame itself is quite small and invisible, so checking for the presence of water vapour is the best approach to ensure that flame ignition has been successful. This can be done by holding a cold mirror above the outlet of the detector and observing condensation of the water vapour. Deterioration of performance of a properly operating FID is often the result of having used chlorinated solvents. Soot particles and the presence of HCl eventually lead to high and noisy baselines. The jet tip and collector electrode may have to be cleaned or, if badly corroded, replaced. Some spiking may be observed if portions of the polyimide coating are burned off the end of the capillary column.

The FID is mass flow-sensitive, meaning that the area response for a compound does not change as flow rate is varied. For quantitative work, appropriate response factors must be obtained, especially if a split injection mode is employed. When properly configured, a FID can respond to approximately 20 pg of each component eluting from a high resolution capillary column.

The Thermal Conductivity Detector

The TCD has long been a standby in packed column chromatography. It is a simple device, well suited to routine analyses where it is not necessary to detect low concentrations of components. It has been in use since the beginning of GC and has proven to be a rugged and dependable detector, in part because of the relatively simple electrical requirements. It is often encountered in less expensive instruments, and is the commonly used detector for the analysis of fixed gases. Until the introduction of the FID, it was by far the most common detector in use. Unlike the FID, no additional gases (beyond the carrier gas) are required, which makes it useful in situations where hydrogen gas would be hazardous or where additional gas supplies are not readily available. This may be important in field applications where portability is a factor.

For use with capillary columns, the TCD has been engineered down to a small volume in order to accommodate the need for a response time of the detector that is significantly less than the chromatographic peak width. Competing with this desire for small volume is the practical consideration that TC detectors become more sensitive to external effects as cell volume is decreased. A similar trade-off occurs when use of a make-up gas is warranted in order to help sweep the detector clear of sample, because the resultant sample dilution decreases the voltage difference responsible for the detector response. Currently, cell volumes are in the 100 µL range, suitable for use with 530 µm columns without make-up gas. At least one manufacturer offers a cell volume of less than 5 µL, but still recommends the use of make-up gas so that the total flow through the cell is 5 mL min⁻¹. Thus, the narrow-bore capillary columns can be accommodated, albeit with some loss of sensitivity resulting from the dilution.

The TCD responds to bulk properties of the effluent. It compares the conductivity of a filament exposed to the carrier gas to that of a filament exposed to sample components. The baseline is established by heating the filaments to a constant temperature with carrier gas flowing. Since the thermal conductivity of helium or hydrogen (often used as the carrier gas) is higher than virtually any other material likely to be encountered, the temperature of the filament increases when sample components are present in the effluent. The electronics of the TCD adjusts the current to maintain a constant temperature or allow the temperature to rise and respond to the difference in resistance. In either case the resulting voltage is used as the chromatographic signal based on the assumption that other thermal effects remain constant. The filament itself is constructed from tungsten

Figure 2 Schematic diagram of thermal conductivity detector electronics.

or tungsten–rhenium alloys to take advantage of the high resistance–temperature coefficient. TCD sensitivity increases as the temperature difference between the filament and the detector wall increases. This, coupled with the desire to have relatively low filament temperature (in order to increase lifetime), means that the detector body temperature should be set as low as possible while still preventing sample components from condensing.

Various detector designs incorporate geometries with as many as four filaments. These are often incorporated into a Wheatstone bridge circuit (Figure 2) and produce a voltage imbalance when an analyte passes through one side. In the HP 5890 series II TCD cell depicted in Figure 3 there is a single filament and a switching system so that the gas stream alternates every 200 ms. The response is due to the voltage difference of a filament exposed

Figure 3 HP 5890 series II thermal conductivity cell.

alternatively to pure carrier gas and carrier gas plus sample.

As mentioned above, He and H₂ are commonly used as carrier gases when the TCD is involved. H₂ has a significantly higher thermal conductivity than does He, but is often not chosen because of its potential explosiveness and because it may reduce the oxide coating on the filament and thus cause changes in response factors. Most sample components have thermal conductivities well below that of either hydrogen or helium (Table 1), thus providing a detector with a universal response. Analysis of hydrogen requires special consideration. For instance, N₂ or Ar could be used as a carrier gas, but then sensitivity to other compounds would be much reduced. Alternatively, He can be used as a carrier gas, and the detector temperature kept relatively high.

The TCD is a concentration-dependent detector, so that the peak size is dependent on flow rates. The MDA is much higher than for the FID, corresponding to about 10 p.p.m. of C₉ in the cell. Although response factors cannot be calculated from thermal conductivities alone, they have been determined for many compounds and shown to vary only slightly within a homologous series. This makes the TCD useful for quantitative work. Organometallic compounds have somewhat low response factors, as do halogenated compounds. Some representative response values, relative to benzene, are shown in Table 1.

Operationally the TCD is quite simple, although the filament can be permanently damaged if current is left on without gas flow being maintained. Likewise,

Table 1 Thermal conductivities and TCD response values for selected compounds

Thermal conductivity of common gases (relative to He = 100) ^a	Molar response (in helium) (relative to benzene = 100)

^aTemperature 100°C.

exposure to traces of oxygen is damaging to the filament, so that the system must be leak-free. Use of plastic tubing such as nylon or polytetrafluoroethylene is discouraged since they are permeable to oxygen. Temperature variations in the detector will result in baseline fluctuations so careful control of heating elements is necessary. When properly operating, the noise level is only a few microvolts.

The design of these two detectors has not changed markedly since their introduction over three decades ago and they are firmly entrenched in chromatographic analyses. This will continue to be the case for systems in traditional laboratories. In addition, there has been recent progress in the development of miniature gas chromatographic systems and fast chromatography. This miniaturization has been driven by advances in field analyses and the concomitant need for portability. These systems take advantage of silicon micro machining and integrated circuit-processing techniques, including a microthermal conductivity detector. More information about this can be obtained from the publication by Etiope (see Further Reading).

Detectors: Mass Spectrometry

M. R. Clench and L. W. Tetler, School of Science and Mathematics, Sheffield Hallam University, Sheffield, UK

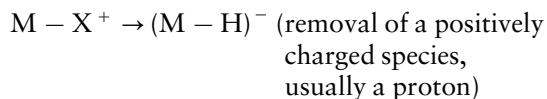

Copyright © 2000 Academic Press

Introduction

The mass spectrometer provides the most powerful detector available for gas chromatography. It is sensitive, selective and offers vastly superior qualitative information over conventional detectors such as the flame ionization detector (FID) or electron-capture detector (ECD). Modern instruments for gas chromatography-mass spectrometry (GC-MS) are small, reliable and much less expensive than formerly. In many laboratories small 'bench-top' GC-MS instruments have virtually replaced 'stand-alone' gas chromatographs for even routine applications. In this short paper we shall attempt to describe some of the basic principles of mass spectrometry and how they are applied in GC-MS. In order to illustrate some of the techniques available the determination of nitrated polycyclic aromatic hydrocarbons in diesel particulates will be utilized as a case study.

Ion Formation

Mass spectrometers are used to analyse ionized sample molecules. There are essentially four methods in which a neutral sample molecule (M) can be converted into an ionic species:

The *ion sources* used in GC-MS make use of each of these four processes in order to form positive or negative ions as appropriate.

Electron Ionization (EI)

The most important method for the production of ions in GC-MS instruments uses the electron ioniza-

tion (EI) ion source. A schematic of a typical EI ion source is shown in **Figure 1**.

The filament, usually a simple coil of tungsten wire, is heated. On heating it produces electrons, which are then accelerated into the ion source chamber by applying a potential difference between the filament and the chamber. This potential difference is usually in the range 50–70 V, giving the electrons a kinetic energy (*the electron energy*) of 50–70 eV (where $1 \text{ eV} = 1.602 \times 10^{-19} \text{ J}$). Interaction of neutral sample molecules with the electrons causes ionization by removal of one electron:

This process creates the positively charged *molecular ion* of the sample molecule, i.e. a radical cation. However, the first ionization energy of most organic compounds is only of the order of 10 eV. Hence molecular ions formed in an EI ion source have excess internal energy and further fragmentation occurs in order to dissipate this energy. Fragmentation occurs via a variety of processes and leads to mass spectra containing a fingerprint of the molecule. The processes of fragmentation are shown below:

and/or:

(where F_1^+ represents an even electron fragment ion, R^\bullet a neutral radical, $F_2^{+\bullet}$ an odd electron fragment ion, often called a radical ion, and N a neutral species).

Figure 1 Schematic of an electron ionization (EI) ion source. Ions formed by interaction of the sample molecules with electrons emitted from the filament are extracted and focused into the mass analyser by the action of the repeller and the focusing lens.

Both types of initial *fragment ions* may also further fragment:

and/or:

Fragmentation will continue until the excess internal energy is dissipated. The appearance of EI mass spectra is a function of the compound under investigation, the electron energy used and the ion source temperature. For this reason it is usual to record EI mass spectra at an electron energy of 70 eV which gives good sensitivity, interpretable fragmentation and allows comparison to be made between spectra recorded on different instruments and with standard spectra stored in computerized libraries.

An EI mass spectrum of 2-nitrofluorene, a nitrated polycyclic aromatic hydrocarbon, is shown in Figure 2A. This mass spectrum illustrates some of the key features of EI spectra. A small molecular ion can be seen at m/z 211 along with fragment ions corresponding to the loss of $\cdot\text{OH}$ and NO_2 groups. The pattern of fragment ions, i.e. their intensity and distribution is characteristic of 2-nitrofluorene and library search, used where possible in combination with GC retention time (obtained from a standard sample), allows the sample to be easily identified.

Figure 2 Comparison of (A) electron ionization, (B) positive chemical ionization and (C) negative chemical ionization mass spectra of 2-nitrofluorene. Note the higher degree of fragmentation in the EI mass spectrum.

Electron ionization is the most widely used ionization technique for GC-MS. However, it has a number of limitations. The most important of these is caused by the excess internal energy of the initially formed molecular ions. For certain classes of compounds, they all fragment in the ion source and hence a molecular ion is not observed in the recorded mass spectrum. This removes one of the key pieces of information from the mass spectrum, i.e. the relative molecular mass of the compound under investigation. In order to overcome this, other ionization techniques are available to the mass spectroscopist, the most important of these being chemical ionization (CI).

Chemical Ionization (CI)

Positive ion chemical ionization In positive ion CI an ion source slightly modified from that shown in Figure 1 (by reduction of the size of the ion exit aperture) is filled with a *reagent* gas (e.g. methane, isobutane or ammonia) to a pressure of about 0.1–1.0 mbar. At this pressure ion–molecule reactions can occur between ions of the gas (created by EI processes) and neutral gas molecules. Taking as an example some of the processes that occur when methane is used as a reagent gas:

In a similar way when sample molecules are introduced into the ion source, ion molecule reactions between reagent gas ions and gaseous sample molecules can occur, to produce sample ions, i.e.

The formation of sample ions via these reactions is much less energetic than molecular ion formation via electron ionization. Hence the mass spectra obtained show less fragmentation than the corresponding EI mass spectra. When methane or isobutane are used as the reagent gas, proton transfer is the dominant reaction. Hence the relative molecular mass of the compound of interest can now be derived from the

$n(M + H)^+$ *protonated molecular species* with additional confirmation of the assignment being given by the presence of the $(M + C_2H_5)^+$ *adduct ion*. Where ammonia is used as the reagent gas electrophilic addition is often as important or the dominant process and in this case the $(M + NH_4)^+$ adduct ion may be used.

Figure 2B shows the positive ion chemical ionization mass spectrum of 2-nitrofluorene obtained using methane as reagent gas. Note the large $(M + H)^+$ peak at m/z 212 and the reduced fragmentation compared to the corresponding EI spectrum. Also visible is the adduct ion at m/z 240 corresponding to the $(M + C_2H_5)^+$ ion formed by the electrophilic addition process discussed earlier.

Negative ion chemical ionization (NCI) Chemical ionization is also a useful way of producing negatively charged species for mass spectrometry. There are two important mechanisms for ion formation in NCI. The first, which is analogous to the processes already described for positive CI, is proton transfer:

This type of reaction will occur when the relative proton affinity of the reagent gas anion (B^-) is high. It is a relatively low energy process and leads to mass spectra containing intense $(M - H)^-$ ions and little fragmentation.

However, a more important mechanism of ion formation in NCI, and one that has been widely utilized in GC-MS, is via an electron capture process. If a compound containing one or more suitable electronegative groups is introduced into the ion source in the presence of a high pressure (~ 1 mbar) of a *buffer gas* (e.g. methane) the following reaction can occur:

In the above equation the thermal electrons (e^{-th}) are produced from the electron ionization of the methane. The neutral methane molecules also act to collisionally stabilize the excited radical anion formed by associative resonance electron capture. This leads to the observation of a radical anion ($M^{\cdot-}$) in mass spectra recorded using this ionization method.

Electron capture is a very low energy process and the recorded mass spectra contain little or no fragmentation. The NCI mass spectrum of 2-nitrofluorene is shown in Figure 2C. This compound contains an electronegative nitro group, and is ionized via the electron capture process. An intense $M^{\cdot-}$ ion can be seen at m/z 211 with no evidence of fragmentation.

In a similar manner to the use of the electron-capture detector for gas chromatography, the use of electron capture NCI GC-MS can introduce sensitivity and specificity into an analysis. Whereas approximately 100 pg of sample are required to record a mass spectrum in EI mode, NCI spectra have been recorded from a little as 500 fg (for appropriate electron capturing compounds). This will be further illustrated below.

The Separation of Ions and Recording of Mass Spectra

There are many methods available for the separation of ions and recording of mass spectra. The ionization methods described above have been incorporated into all of the current commercial types of mass spectrometer. In this section only brief descriptions of these are offered. For a more complete discussion see either Chapman (1993) or Johnstone and Rose (1996).

The key parameters to take into account in the selection of a particular type of mass spectrometer for a GC-MS experiment are the masses of the compounds under consideration and the selectivity and sensitivity required for the analysis. Where the largest compounds to be encountered are likely to have a relative molecular mass of less than 1000 any of the types of mass spectrometer described below is useful.

The Quadrupole Mass Filter

The quadrupole mass filter is the most widely employed type of mass analyser in current use. It comprises four metal rods accurately aligned around a central axis. RF and DC voltages on the rods create a complex electrostatic field within the area bound by them. Ions entering this region are acted on by the electrostatic field and their motion through the rods can be likened to two superimposed sine waves. Under these conditions the forces acting on most ions cause the amplitude of the oscillations to increase and accelerate them into the quadrupole rods. However, some ions are not accelerated into the rods and undergo trajectories that traverse the full length of the rods. The parameters that govern the equations of motion of ions in a quadrupole mass filter are the mass to charge ratio of the ions, the spacing between the rods, the frequency of the RF voltage and the magnitude of the RF and DC voltages. Hence the RF and DC voltages may be selected such that ions of only one m/z value have 'stable' trajectories. By varying the RF and DC voltages but keeping the ratio between them the same a range of m/z values can be made to undergo stable trajectories, be brought to focus on the detector and a mass spectrum recorded.

The Ion Trap

The ion trap operates in a similar manner to a quadrupole mass filter. It comprises a doughnut-shaped ring electrode to which the RF voltage is applied and two end caps either earthed or with supplementary AC or DC voltages. Ions formed either in the trap, or externally to the trap and transported into it, are initially stored within the trap. Mass separation is then achieved by increasing the RF voltage such that ions are ejected from the trap in ascending m/z order.

The Double Focusing Magnetic Sector Mass Spectrometer

The double focusing magnetic sector mass spectrometer differs from those discussed so far in that the mass analyser comprises two distinct components, an electromagnet and an electrostatic analyser. The magnet acts as a momentum analyser and affects mass separation, while the addition of an electrostatic analyser corrects for some variations in the kinetic energy of ions of the same m/z value and allows them to be brought to focus on the detector at the same time. Hence the use of a double focusing arrangement as a mass analyser allows very high *resolution* to be achieved. In mass spectrometry resolution is defined as the ability of the mass spectrometer to separate ions of very similar m/z value.

Resolution is important in mass spectrometry since it may be used to introduce specificity into an experiment. An important application of high resolution arises in the determination of polychlorinated dibenzodioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs) by GC-MS. These compounds are found ubiquitously in the environment and their determination is important owing to concern about their toxicity, mutagenicity and carcinogenicity. The only method that has been found to offer the appropriate degree of sensitivity and specificity for this analysis is GC followed by high resolution MS detection. High resolution is required since matrices which accumulate PCDDs and PCDFs are also likely to accumulate other polychlorinated aromatic hydrocarbons, e.g. polychlorinated biphenyls. These compounds, which may co-elute with the PCDDs and PCDFs of interest, contain fragment ions in their EI mass spectra which have the same integer m/z value as the molecular ions of PCDDs and PCDFs. However, by monitoring the accurate mass value of the PCDD and PCDF molecular ions (i.e. the exact mass value of their elemental composition), at an adequate resolution to separate them from likely interfering ions, specificity is introduced. GC-MS is used extensively in environmental analysis for a range of ap-

plications including dioxin analysis. For further details the interested reader is referred to Bruner (1993).

Interfacing Mass Spectrometers with Gas Chromatographs

There are several methods available for interfacing gas chromatographs with mass spectrometers. These include the use of jet separators for packed columns and a variety of ways of interfacing capillary columns. For packed columns the jet separator, a form of momentum separator, is required to remove the majority of the carrier gas. A 'solvent dump valve' is also incorporated into these devices in order that the injection solvent can be vented to waste rather than it passing into the mass spectrometer.

Although a number of interfaces for packed column GC-MS have been described in the past, capillary columns are currently almost exclusively used for GC-MS. The most widely used interface, in this case, is the direct interface, where the column is passed through a simple heated transfer line directly into an EI or CI ion source. The low (1 mL min^{-1}) carrier gas flow commonly used with capillary columns can readily be accommodated by the MS pumping system in order to maintain a good vacuum. **Figure 3** shows a complete instrument based around the use of a capillary column, a simple direct interface and a quadrupole mass spectrometer. For a more complete discussion of the full range of GC-MS interfaces see either Chapman (1993) or Johnstone and Rose (1996).

GC-MS Experiments

Full or Normal Scan

The standard GC-MS mode of operation is the full or normal scan mode. On injection of the sample into the GC, the mass spectrometer is set to repetitively scan over a preset mass range. Typically this would involve the mass spectrometer recording a mass spectrum over the scan range 35–500 Da once a second.

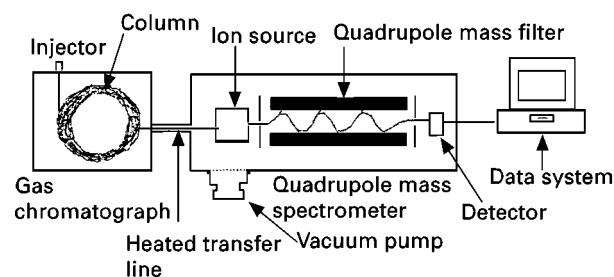

Figure 3 A quadrupole based GC-MS instrument employing a direct interface for connection between the GC and the MS.

The requirement for relatively fast acquisition rates is due to the fact that open tubular GC columns typically produce peaks of only about 10–15 s wide. Hence, in order to acquire a representative number of mass spectra from each peak, fast scan rates are required. A second consequence of these fast acquisition rates is the requirement for a data system on all GC-MS instruments. Each mass spectrum can then be stored in the data system for subsequent examination/data processing.

Full scan data are used by the data system to generate a total ion chromatogram (TIC). This is achieved by summing the intensity of the ions in each mass spectrum to create a value for the total ion intensity, as a number of ions or total number of analogue to digital converter bits. This number is then plotted against time/scan number to create a chromatogram. One of the great strengths of GC-MS using EI ionization is that the TIC generated by this method is then directly comparable with a chromatogram produced from the same sample using flame ionization detection.

Selected Ion Monitoring (SIM)

Selected ion monitoring (SIM) is a technique widely used for trace analysis. In this technique, rather than the mass spectrometer being set to scan over a pre-defined mass range and record full mass spectra it is set to monitor the intensity of specific m/z values. SIM is used to introduce selectivity into an analysis and improve sensitivity. Sensitivity is enhanced over the full scan mode experiment since in the full scan experiment a large proportion of the scan time is spent recording areas of the spectrum where no ions of interest occur. Ions are still being produced in the ion source but are lost in the mass analyser as it brings others into focus on the detector. In SIM, in a 1 s duty cycle, only a few, i.e. 1–10, ions are selected. Hence, the mass analyser transmits these ions for a longer percentage of the time in which they are being produced and therefore more of the ions of the particular m/z values of interest are recorded.

SIM may also be used to introduce selectivity into the experiment. This also has the effect of increasing sensitivity by decreasing the amount of 'chemical noise', i.e. real signal, but not from the compound of interest, observed when peaks of interest elute. The increase in selectivity may also be achieved by the use of a double focusing mass spectrometer and high resolution and this may be enhanced by, for example, the use of negative chemical ionization.

An example of the increase in selectivity obtained by the use of SIM combined with NCI from our own laboratory can be seen in the determination of nit-

rated polycyclic aromatic hydrocarbons (nitro-PAH) in vegetation extracts. Nitro-PAH are absorbed on to vegetation from anthropogenic emissions, however their determination is made complex by the large amount of other compounds extracted from the vegetation by the sample preparation procedure. Figures 4A and B show a comparison between the chromatogram obtained from an extract of bark from a maple tree in an urban region using an ECD and the individual mass chromatograms obtained from the same extract using GC-MS in NCI-SIM mode. The

Figure 4 A comparison of the chromatograms obtained from the analysis of a complex extract containing nitrated polycyclic aromatic hydrocarbons by gas chromatography (A) using an electron-capture detector and (B) by GC-MS employing negative chemical ionization and selected ion monitoring. Note the increase in specificity afforded by the use of GC-MS under these conditions.

quadrupole mass spectrometer used in this case was set to monitor the M^+ ions obtained from 9 nitro-PAH. The complex chromatogram shown in Figure 4A does not allow simple identification of the peaks of interest and the possibility of interferences/peak overlap leads to difficulties when attempting quantification. This can be observed for peak 5 ($t_r = 34.1$ min) in Figure 4A. This peak arises from the presence of 2-nitrofluorene in the bark extract. As can be seen, accurate and precise integration of this peak is made difficult by the presence of peaks with very similar retention time. In contrast the peaks from the nitro-PAH monitored by NCI-SIM can be seen clearly in Figure 4B. Each chromatographic trace in this figure represents the ion current observed from monitoring the m/z value of the M^+ ion of a series of nitro-PAH. Peaks are readily integrated for quantification with the 2-nitrofluorene peak (peak 5) appearing well resolved on the m/z 211 trace.

One of many areas in which the use of resolution to introduce specificity into SIM experiments is important is the petroleum industry. Dibenzothiophenes (DBT) have been suggested as marker compounds for oil pollution. However, taking as an example dibenzothiophene itself, this has the same nominal molecular mass (184 Da) as the C_4 -alkylated naphthalenes which are also present in crude oil. Hence in order to specifically measure dibenzothiophene in crude oil it is necessary to monitor the accurate mass to charge ratio (m/z 184.0347) of its molecular ion at high resolution in a SIM experiment. Figure 5 compares the GC-MS-SIM analysis of dibenzothiophene in crude oil carried out using low and high resolution. As can be clearly seen the C_4 -naphthalenes are not observed in the high resolution data. The power of such analyses can be seen in Figure 6 which shows a comparison of the GC-HRMS-SIM data obtained from the analysis of methyl and C_2 substituted dibenzothiophenes for three different crude oils obtained from two North Sea oil fields. The different crude oils can be clearly distinguished with such data.

Other Techniques

Mass Spectrometry–Mass Spectrometry (MS-MS)

Mass spectrometry–mass spectrometry, also known as tandem mass spectrometry, is the term used to describe mass spectrometric methods employing instruments that contain more than one mass analyser. Such instruments may be used to increase the amount of structural information obtained or to introduce more specificity.

The simplest tandem mass spectrometer to consider is the triple quadrupole mass spectrometer. This com-

Figure 5 GC-MS analysis of dibenzothiophene (DBT) in a crude oil using low resolution (top) and high resolution (bottom) selected ion monitoring. (Reproduced from Tibbets and Large (1988) by kind permission of John Wiley and Sons.)

prises two quadrupole mass filters and a multipole collision cell and is shown schematically in Figure 7. In principle the operation of such an instrument follows the following sequence: ion selection in the first quadrupole mass filter, ion dissociation in the collision cell and separation of the products of ion dissociation in the second quadrupole mass filter. For illustration, Figure 2C, the NCI mass spectrum of 2-nitrofluorene, only contains the M^+ ion at m/z 211. Hence the only information contained in this mass spectrum is the relative molecular mass of the compound. In order to generate structural information a *product ion scan* could be carried out. To do this the first quadrupole mass filter would be set to transmit only m/z 211. This ion would then be subjected to collisions with a gas held in the collision cell (collisionally induced decomposition (CID)) and the resulting *product ions* recorded using the second quadrupole mass filter. The resulting *product ion spectrum* then shows only ions that have arisen

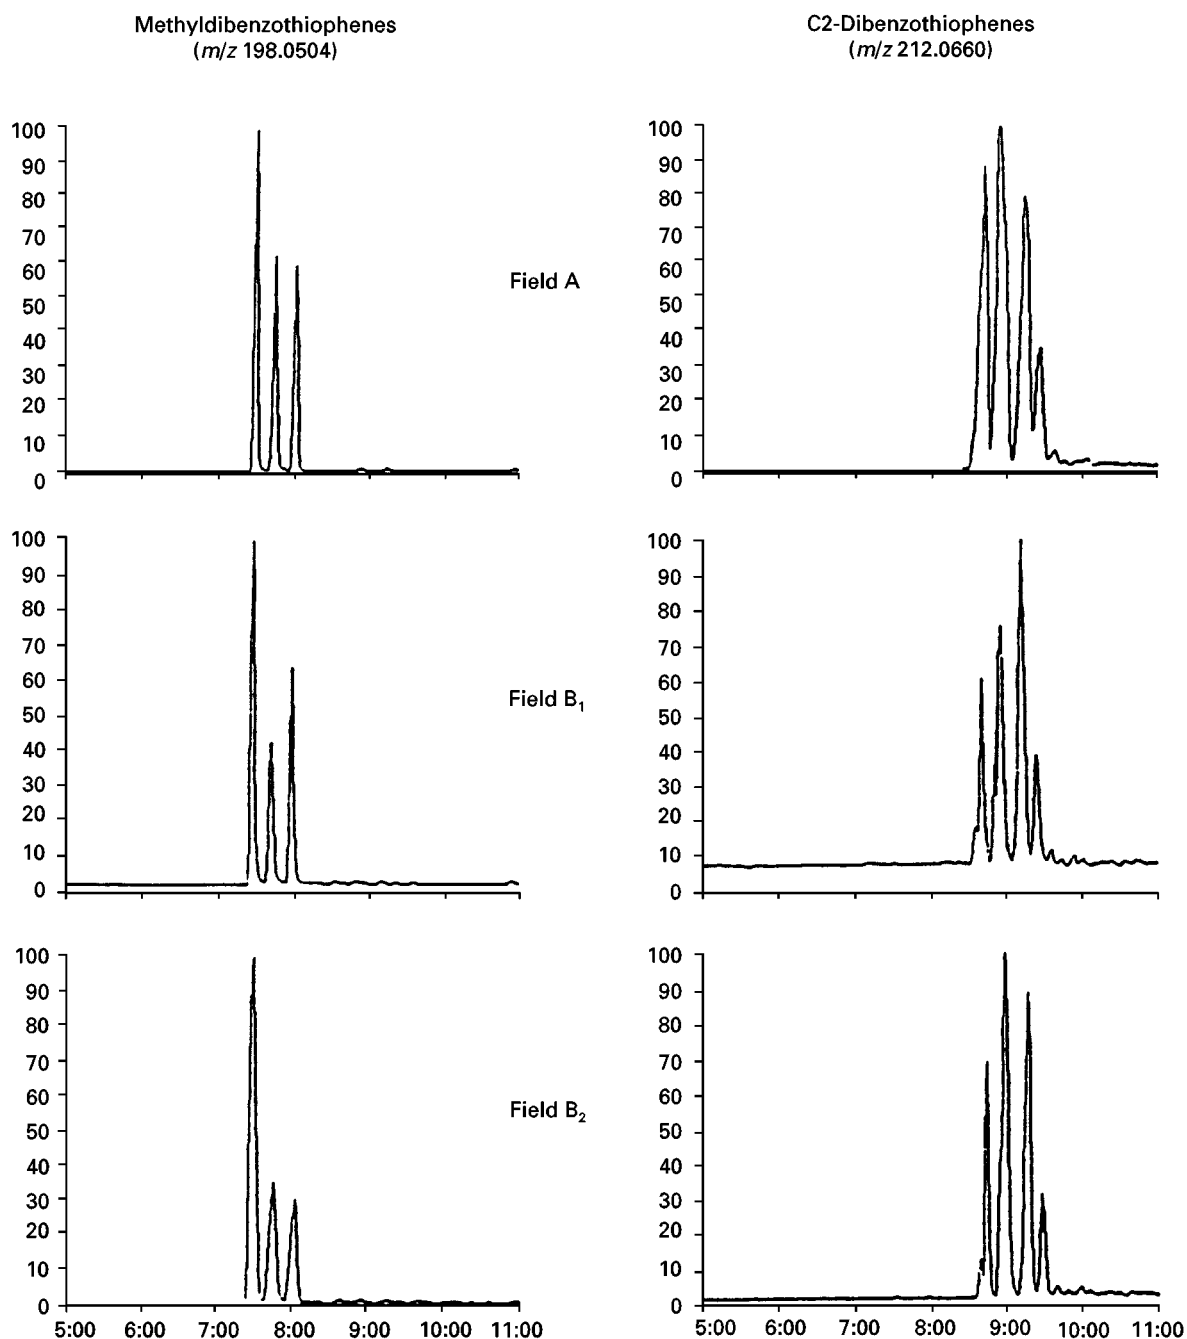

Figure 6 A comparison of the GC-HRMS-SIM fingerprints of methyldibenzothiophenes and C_2 -dibenzothiophenes in three crude oils from two North Sea fields. (Reproduced from Tibbets and Large (1988) by kind permission of John Wiley and Sons.)

directly from the fragmentation of m/z 211 and contains structural information. It can be seen that this method is also useful for clearing up ambiguities in the interpretation of EI spectra, since it allows *precursor/product ion* relationships to be clearly defined.

A second application of tandem mass spectrometry often used in conjunction with GC-MS utilizes a technique called *multiple reaction monitoring* (MRM). This technique, like high resolution SIM, is used to

increase the specificity of an analysis. After first recording product ion mass spectra of the analyte(s) of interest, one or more precursor/product ion relationships are chosen. The criteria for this are that the product ions selected are intense and characteristic of the specified analyte. Then in order to carry out the MRM experiment, the first quadrupole mass analyser is set up in SIM mode, to switch between the precursor ions of interest. The collision cell is operated in

Figure 7 A triple quadrupole mass spectrometer. On leaving the GC column sample components are first ionized, then ions selected by the first quadrupole mass filter are fragmented in the collision cell for analysis by the second quadrupole mass filter. Such instruments may yield greater structural information than single stage instruments and allow further selectivity to be introduced into GC-MS experiments.

the normal way, and the second quadrupole mass filter is set up to switch between the characteristic product ions.

The output from such an experiment is chromatographic, producing one or more plots of signal intensity against time. Peaks are only observed in such chromatograms when an ionized compound yields an ion of the selected precursor ion m/z value, which also subsequently fragments, under CID, to give a product ion of the selected product ion m/z . The two stages of mass selection make this a highly selective technique and it has been proposed as a viable alternative to high resolution SIM for a variety of applications.

Recent advances in ion trap technology have meant that similar modes of operation also available on these compact, relatively low cost instruments. In this case ions other than the precursor ion of interest are selectively ejected from the trap. The selected precursor ion is then subjected to CID in the trap and a product ion mass spectrum may be recorded by ejecting these ions. For a fuller discussion of tandem mass spectrometry see Busch *et al.* (1988).

Conclusions

A developing field in GC-MS is the use of time of flight mass analysers with short capillary columns for very rapid analyses. We have described time of flight mass analysers and the advantages offered by their use for the acquisition of mass spectral data from narrow chromatographic/electrophoretic peaks in the companion paper to this one, on the use of mass spectrometry as a detector for liquid chromatography. The same arguments apply for fast GC-MS analyses and a number of manufacturers have recently launched instruments of this type. Specialist GC-MS instrumentation is also increasingly being used in the

clinical field in order to accurately determine isotope ratios, e.g. the presence of *Helicobacter pylori* in the gastric epithelium has been linked with gastritis, peptic ulcers and gastric cancer. The presence of *Helicobacter pylori* can be determined by measuring the $^{13}\text{C}/^{12}\text{C}$ isotope ratio in exhaled breath following ingestion of isotopically labelled urea. Gerhards *et al.* (1999) have examined the use of GC-MS in clinical analysis and Platzner (1997) provides a full discussion of modern isotope ratio mass spectrometry.

The future of mass spectrometry as the detector of choice for gas chromatography looks secure. In this paper we have illustrated some of the benefits of this happy marriage of techniques. Modern GC-MS instruments are compact, robust, sensitive, selective and give access to a range of information not possible when using conventional detectors, hence their importance in the modern GC laboratory.

Detectors: Selective

E. R. Adlard, Burton, South Wirral, UK

Copyright © 2000 Academic Press

Introduction

The packed columns used in the early days of GC were inefficient by modern standards and so selective detectors that only gave a response to particular elements or compounds had obvious advantages when analysing complex mixtures. There was also a big incentive to develop more sensitive detectors and the detection of an organic vapour in an inert gas lent itself to the development of a host of devices, the majority of which have failed to make any lasting impact. Even today when the mass spectrometer is the selective detector *par excellence* there are still a number of other, more limited, detectors commercially available and this situation seems likely to continue. This paper describes some of these detectors; it should be noted that they are described as 'selective' rather than 'specific' since although they may give a large signal for one type of analyte they will also invariably give a small signal for others.

In general, selective detectors usually have more operating parameters than the two common universal detectors, the thermal conductivity detector (TCD) and the flame ionization detector (FID), and are more sensitive to small changes in these parameters. Some selective detectors are so temperamental that, having needed several days to set them up, they are then best left in continuous standby even when not in use.

Element-Selective Detectors

Although there are selective detectors for most elements, the common ones are those for sulfur, nitrogen, phosphorus and the halogens. These elements account for the great majority of published work because they are the ones most likely to be encountered in most real life applications.

Sulfur-Selective Detectors

Sulfur is an important element which turns up in many fields usually with deleterious effects; 0.1 ppm of a mercaptan in isopropyl alcohol would, for example, render it totally unfit for perfumery applications.

The flame photometric detector (FPD) monitors the light emitted by a hydrogen-rich 'cold' flame. Under these conditions sulfur (the S_2 species) has a band

spectrum with a maximum at 394 nm and phosphorus (HPO) has a band spectrum with a maximum at about 526 nm. Since these are band spectra they do not exhibit the very sharp emission lines of atomic spectra and are, therefore, only moderately selective. There are carbon band spectra, for example at 388 nm, that tend to interfere with the sulfur spectrum. The response is approximately equimolar for different sulfur compounds unless oxygen is also present in the molecule. Since it is an S_2 species being monitored in the flame the response is approximately proportional to the square root of the concentration. This disadvantage can be catered for by suitable electronics but there is always some doubt about whether the response follows the square root relationship accurately and calibration is essential for reliable quantitative results. Another severe disadvantage of the simple FPD is that co-eluted organic compounds not containing sulfur will 'quench' the sulfur emission and cause a drastic diminution of signal.

In spite of these disadvantages the FPD has proved a popular and important detector especially in the food and petroleum industries. For example, in the former it has been used for the detection of mercaptans in lager. In the latter it has been shown that a crude oil, so biodegraded that it can no longer be identified by its hydrocarbon fingerprint, can still be recognized by its sulfur fingerprint since the sulfur compounds are much more slowly degraded.

There have been a number of attempts over the years to improve the performance of the FPD. A dual-flame version oxidizes the sulfur compounds to SO_x in an ordinary oxidizing flame and the products of combustion are then taken to the hydrogen-rich cold flame. This gives a considerable reduction in the quenching effect of co-eluting compounds but at the cost of at least 10-fold loss in sensitivity from about 10^{-9} g s^{-1} for the single flame version. Another version, the pulsed FPD, developed by Amirav *et al.* in 1991, reduced the hydrogen flow rate so that the flame is extinguished and re-ignited about 2–4 times a second. The emission during each period of emission is scanned from the time of ignition and electronically time-gated. Under these conditions it is possible to discriminate on a time basis between carbon emissions taking place at 2–3 ms after ignition and sulfur emissions which take place at about 6 ms. Thus with this design there is both wavelength and time discrimination and the combined effect is a very high selectivity and a sub-picogram per second sensitivity. In spite of these advantages there are few publications on the use of the PFPD to date.

Most versions of the FPD can be used for phosphorus detection by changing the filter from 394 nm for S to 526 nm for P and a number of other elements such as Se, Sn, As and Ge have also been determined at various wavelengths and with varying degrees of selectivity and sensitivity. Simultaneous detection of two elements is also possible.

A different type of sulfur/nitrogen selective detector has been successfully developed in the last few years. In the sulfur chemiluminescence detector (SCD), the sulfur-containing compounds are combusted in an oxidizing flame or in later versions in a miniature ceramic furnace to SO_x which is then reacted with ozone in a low pressure chamber at about 10–15 Torr. Reaction with ozone raises the sulfur oxides to an excited state and as the molecules drop back to the ground state they emit light in the far blue end of the spectrum which is monitored by a photomultiplier tube after passing through an optical filter. Sub-picogram per second sensitivity is claimed for this detector with a linear response over five orders of magnitude, equimolar response for different sulfur compounds and no quenching effects. By replacing the optical filter for sulfur with one in the red region (610 nm) the detector can be used selectively for nitrogen. This is, in effect, similar to the so-called Thermal Energy AnalyserTM which was produced in the 1970s specifically for the analysis of nitrosamines in food but which never achieved wide popularity.

Figures 1A–D show chromatograms of a gas oil before and after a hydrotreater unit designed to reduce the total sulfur content of the fuel from about 220 ppm to 2 ppm. Figures 1A and B show the before and after FID traces where it is difficult to see any difference and Figures 1C and D show the before and after SCD chromatograms where the difference is clearly apparent.

Nitrogen-Selective Detectors

To a certain extent these have been covered in the section above but the commonest nitrogen-selective detector is the flame thermionic detector. This is abbreviated to FTD or NPD, since by operating under different conditions the detector can be made selective for nitrogen or phosphorus (but not both simultaneously). Like the FPD this detector has a long history of development originating in the observation that alkali metal compounds introduced into a flame gave a high response for halogens. Indeed, early detectors were made by modifying leak detectors used to monitor the escape of halogenated gases from refrigeration units. By operating under different conditions, selectivity for nitrogen and phosphorus could also be obtained. The next development was to use a small

flame as in an FID to impinge upon a pellet of an alkali metal salt; later versions had an alkali metal salt flame tip. All these versions suffered from the fact that, as the salt was gradually vaporized in the flame, the response of the detector altered and consequently required frequent calibration. The current version looks very similar to a conventional FID in construction but has a bead of rubidium glass that can be electrically heated to 600–800°C between the flame jet and the main collector electrode. This acts in a somewhat analogous manner to the grid in an electronic triode valve. Since the bead does not depend on a combustion flame for heating it is more stable and less susceptible to variations in response. For nitrogen the hydrogen gas supply to the detector is very small (about 4 mL min⁻¹) and the area of reaction is described as a hydrogen plasma rather than a flame. Increasing the hydrogen flow rate to the flame to about 30 mL min⁻¹ increases the sensitivity for phosphorus and reduces the nitrogen response. Typical performance characteristics for the NPD are shown in Table 1.

There is still considerable controversy about the mechanism of response of the NPD and for an in-depth discussion of this the reader should consult Patterson (see Further Reading).

The NPD is capable of giving excellent results if used by a skilled operator and it has been used in the nitrogen mode for a wide variety of samples. However, the difficulties in its use for routine analysis and the alternative detectors now available seem to indicate a decline in its use in the future.

Figure 2A shows an FID chromatogram of a sample containing 2 ng amounts of cocaine and heroin and Figure 2B shows the equivalent chromatogram obtained with an NPD. The improved sensitivity and selectivity of the NPD are clearly demonstrated.

Multi-Element Selective Detectors

There are at least two detectors commercially available that are capable of multi-element detection. The first of these is the electrolytic conductivity detector (ELCD), sometimes known as the Hall detector after its main developer and the second is the microwave plasma detector.

The Electrolytic Conductivity Detector (ELCD)

This detector can be used for halogens, nitrogen and sulfur but not for all three simultaneously. The principle of operation of the ELCD is extremely simple. The gases eluting from the column are passed with hydrogen through a small nickel furnace heated to

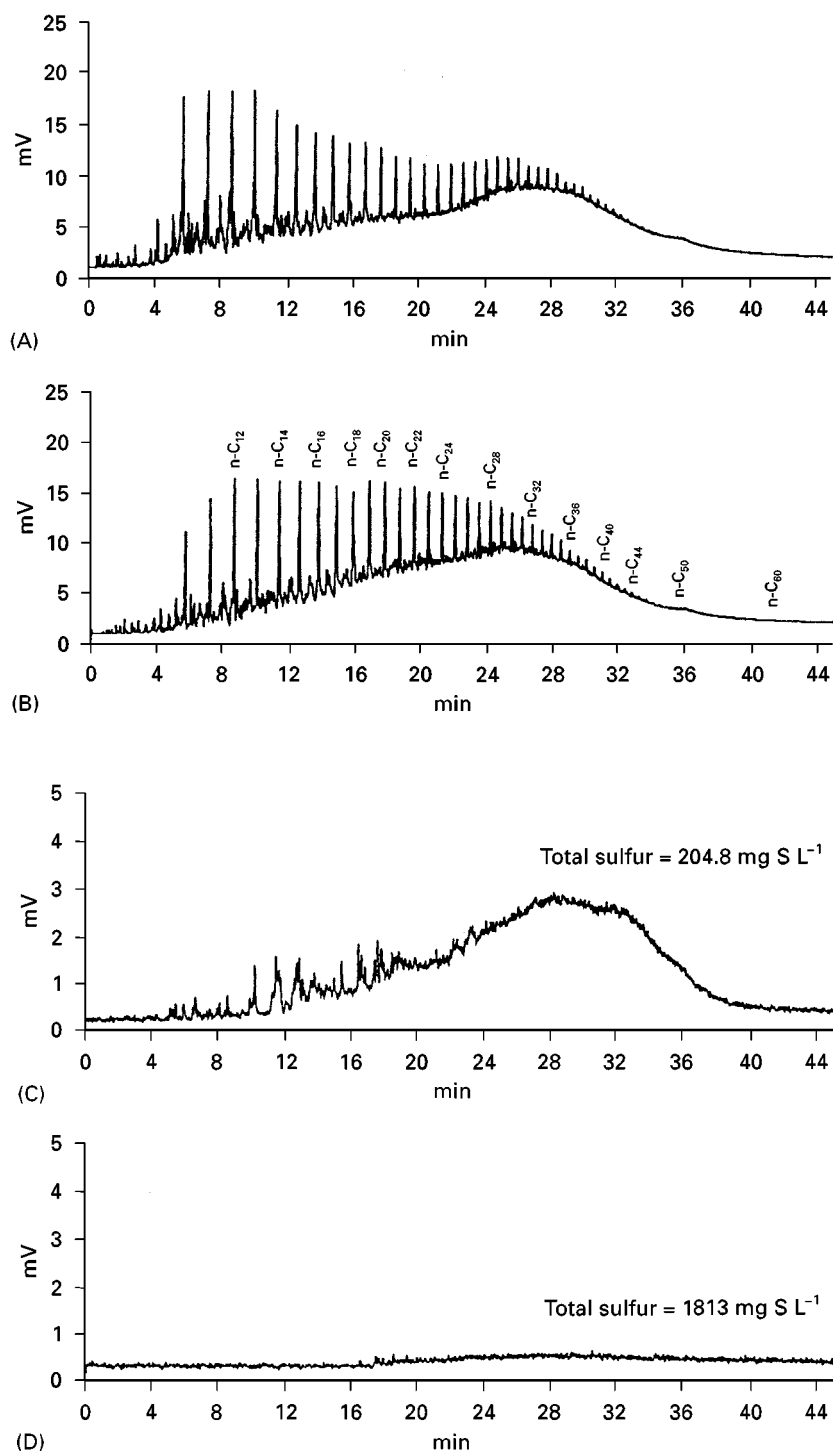

Figure 1 FID chromatograms of gas oil before (A) and after (B) hydrotreating. SCD chromatograms of gas oil before (C) and after (D) hydrotreating. (From Hutte RS. In *Chromatography in the Petroleum Industry* (1995) Adlard ER (ed.). Reproduced with permission of Elsevier Science.)

about 850–1000°C. Under these conditions halogen compounds are reduced to HX, nitrogen compounds to NH₃ and sulfur compounds to H₂S. These gases are all very soluble in water and if they are passed into a circulating water stream the electrical conductivity

will show major changes as the gases emerge. It is also possible to operate in an oxidizing mode so that sulfur goes to SO_x, halogens to HX and nitrogen to N₂.

In practice the equipment is complicated by the fact that the system outlined above would give an integral

Table 1 Typical performance characteristics for the NPD

Characteristic	Typical values
Sensitivity	$S_N = 0.1\text{--}1.0 \text{ A} \cdot \text{s/g N}$ $S_P = 1.0\text{--}10.0 \text{ A} \cdot \text{s/g P}$
Detectivity	$D_N = 5 \times 10^{-14}\text{--}2 \times 10^{-13} \text{ g N s}^{-1}$ $D_P = 1 \times 10^{-14}\text{--}2 \times 10^{-13} \text{ g P s}^{-1}$
Specificity	$S_N/S_C = 10^3\text{--}10^5 \text{ gC/gN}$ $S_P/S_C = 10^4\text{--}5 \times 10^5 \text{ gC/gP}$ $S_N/S_P = 0.1\text{--}0.5 \text{ gP/gN}$
Linear range	$10^3\text{--}10^5$

chromatogram rather than the more familiar differential chromatogram and this is overcome by circulating the electrolyte through ion exchange resins to constantly regenerate pure electrolyte. Selectivity for

Figure 2 Comparison of FID and NPD chromatograms for a sample containing trace amounts of cocaine and heroin. (From Patterson PL. In *Detectors for Capillary Chromatography* (1992) Hill HH and McMinn DG (eds). Reproduced with permission of John Wiley & Sons, Inc.)

halogens co-emerging with nitrogen or sulfur compounds can be obtained by using other electrolytes rather than water (n-propanol is recommended since other reaction gases are not soluble in it). Another way to obtain selectivity is to use small scrubbers containing chemicals that will remove specific gases. For example an acidic scrubber removes ammonia but allow halogen acids to pass through.

Clearly there are number of opportunities for variation in the chemistries involved (material of reaction tube construction, reaction tube temperature, oxidation or reduction, electrolyte and scrubber) in order to obtain optimum sensitivity and selectivity. For halogens the sensitivity is in the low picogram range with a linearity of five orders of magnitude and a halogen/hydrocarbon selectivity of better than 10^6 . In spite of these impressive performance figures the main use of the ELCD has been in the determination of halogenated compounds in water where its use is specified in US Environmental Protection Agency Method 502.2. **Figure 3** shows a chromatogram obtained by purge and trap sampling of water with the ELCD in the halogen mode.

Like the NPD it seems probable that the application of this detector will decline in the future. As separations tend to become faster it is doubtful if the ELCD is capable of providing the rapid response and low dead volume required in such circumstances.

Figure 3 Chromatogram obtained by purge and trap sampling of water with the ELCD in the halogen mode. (From Hall RC. In *Detectors for Capillary Chromatography* (1992) Hill HH and McMinn DG (eds.). ELCD conditions: reactor temperature, 960°C; electrolyte, 35 μ L min⁻¹ n-propyl alcohol; reaction gas, 100 mL min⁻¹ H₂.

The Atomic Emission Detector (AED)

Most of the detectors described above can be used selectively for several elements but this is normally carried out one element at a time, although the FPD, for example, can determine at least two elements (S and P) simultaneously if desired. One of the advantages of the AED is that theoretically it can detect a large number of elements simultaneously with high sensitivity and selectivity. In practice the number determined simultaneously is usually limited to four and, since one of these is normally a carbon channel, only three other elements can be determined.

In the AED, or microwave plasma detector, the compounds are subjected to a high energy microwave plasma so that the emitted spectra are line spectra which are of an extremely narrow wavelength, often only 0.1 Å wide. This results in (potentially) a much higher selectivity and sensitivity.

The AED had a long history of development. It first appeared commercially in the early 1970s. This detector was operated with a microwave plasma in pure helium at low pressure (10–100 mm) and made use of a nitrogen purge to remove carbon deposits from the wall of the silica discharge tube at the outlet of the column. The emission spectra were resolved with a conventional $\frac{3}{4}$ m optical spectrometer which resulted in a rather large and unwieldy apparatus which was also sensitive to movement, requiring fairly frequent realignment of the optics. One of the claimed advantages of this detector was that it was possible to obtain the carbon, hydrogen and other element contents of an unknown molecule and so calculate an empirical formula. In practice it was found to give an empirical formula for low molecular weight compounds that was accurate to about $\pm 10\%$ and the equipment was never really seriously used for this purpose. Sensitivity and selectivity varied considerably from one element to another. In favourable cases such as the halogens, picogram per second levels could be detected with a selectivity over carbon of about 10^3 but nitrogen and oxygen gave much poorer performance mainly due to the large background signal.

A new version was made commercially available in the 1980s. This version differs from the original in two main respects – firstly the microwave discharge takes place in a cavity at atmospheric pressure and secondly the optical spectrometer is replaced by a photodiode array. The result of these modifications is a detector that is much smaller and easier to operate although the actual performance in terms of sensitivity and selectivity is not greatly different from the original designs. The relative compactness and ease of operation have led to a resurgence of interest in this

detector but it is not cheap and as GC-MS systems come down in price they represent strong competition. The definitive account of the various forms of microwave plasma detector is given by de Wit and Beens (see Further Reading).

The Oxygen Selective Detector (O-FID)

The phasing out of lead antiknock compounds in gasoline and their replacement by ‘oxygenates’ – mainly alcohols and ethers such as methyl tertiary butyl ether (MTBE) – created a need for an oxygen-selective detector, easy to use with capillary columns. The O-FID was first proposed by Schneider in 1982 and is now commercially available. The principle of the detector is that the effluent from the GC column is first passed through a microfurnace made of platinum/rhodium alloy heated to about 1200°C where hydrocarbons are cracked to carbon (which is deposited on the Pt/Rh tubing) and hydrogen. Oxygenated compounds on the other hand form CO which is then passed to a second microreactor with a stream of hydrogen. The microreactor containing nickel deposited on alumina is heated to about 350°C and is small enough to fit into the body of a standard FID. Under these conditions each CO molecule is reduced to a methane molecule so that every oxygen atom in the original effluent peak produces one methane molecule. The whole arrangement sounds complex but it works remarkably well for samples up to 20 µg which is of course satisfactory for capillary columns. The detector is ideally suited for the purpose for which it was designed. **Figure 4** shows an O-FID chromatogram of a gasoline sample containing alcohols, water, ethers and acetone. It should be noted that the detector gives a quite respectable peak from the oxygen in the water.

The disadvantages of the detector are its relatively low concentration sensitivity and linearity compared to other selective detectors and the ordinary FID. The limit of concentration sensitivity is about 0.01%.

Other Element-Selective Detectors

A number of organometallic compounds such as those of tin, lead, arsenic and mercury are readily separated by GC and many more as chelate derivatives. Even such an unlikely element as iron can be dealt with as the volatile chloride, FeCl₃, although there are many better methods for such an analysis. For organometallic compounds, atomic absorption and emission spectrometers (AAS and AES), have been used with considerable success. In view of the fact that the vapour emerging from a GC column would appear to be in an ideal state for presentation

Figure 4 Detection of oxygenates in gasoline at 200 ppm level. (From Sironi, A and Verga, GR. In *Chromatography in the Petroleum Industry* (1995) Adlard, ER (ed.). Reproduced with permission of Elsevier Science Publishers.)

to an AAS it is a little surprising that the technique has not been used more frequently. It has the virtues of high sensitivity for many metals and high selectivity. It also gives information about the speciation of the organometallics which is very difficult to obtain in other ways.

In spite of these advantages relatively little has been published on the use of such detection systems, probably reflecting the relatively minor importance of the analysis of organometallics compared to ordinary organic compounds. Organometallics are, however, important in a number of fields, e.g. the determination of butyltin antifouling paint residues in the environment, and it seems likely that this niche area will remain but not expand significantly in the future.

Compound-Selective Detectors

This category refers to detectors that respond specifically to whole molecules or, more commonly, to various functional groups in a molecule.

An example of a detector responding to functional groups is the automatic titrimeter described by James and Martin in their earliest publications on the separation of the lower fatty acids. Although slow and

lacking in sensitivity by modern standards, this detector represented a major advance at the time. Attempts over the years to use microcoulometers as detectors for compounds capable of oxidation or reduction at suitable electrodes have virtually disappeared since, in general, they have slow response and the electrodes are subject of contamination.

Compared to element-selective detectors, there are very few compound-selective detectors and indeed in terms of modern commercially available equipment they can be limited to four – the electron-capture detector (ECD), the photoionization detector (PID) and two spectroscopic detectors, Fourier transform infrared (FTIR) and ultraviolet (UV) detectors. Trapping out polynuclear aromatic hydrocarbon fractions for further analysis by UV spectroscopy was reported many years ago but although there is now an online GC-UV instrument on the market, it is of limited application and will not be discussed further.

The Electron-Capture Detector (ECD)

The development of the ECD by Lovelock in the late 1950s led to its application in environmental studies and the discovery of the wide distribution of chlorinated pesticide residues such as DDT. This was followed by the discovery of the emission of methyl iodide from open ocean waters which again had great significance in the study of the Earth's ecosystem.

The ECD has evolved over many years into an instrument very different in detail from the original even though the principle of detection remains the same. The ionization cross-section detector used a small radioactive source to produce electrons in a cell with two electrodes with about 100 V between them. This caused a small current to flow in the cell as a result of ionization of carrier gas molecules by collision. Compounds eluting from the GC column were ionized to different amounts depending on the cross-section of ionization for each compound. The net result was a variation in the current flowing in the cell which could be recorded electronically. Lovelock modified this detector, firstly by using argon as the carrier gas and secondly by using a much higher voltage (≈ 1000 V) across the electrodes. Under these conditions, multiple ionization takes place via excited argon atoms so that there is a small standing current but a very much larger signal current than given by the cross-section detector. After the argon detector had been on the market for some time, anomalous results were reported especially for halogenated compounds. On investigation, Lovelock concluded that compounds with a strong electron affinity such as polyhalogenated compounds were capturing electrons and thereby reducing the signal

from the detector. He, therefore, maximized the electron capturing effect by using argon with 5–10% methane as carrier gas and about 50 V across the electrodes. Such a cell has a phenomenally high sensitivity for compounds such as CCl_4 and is capable of detecting femtogram quantities (10^{-15} g). Indeed the ECD has a higher sensitivity under favourable conditions than any other detector with the possible exception of radioactivity detectors.

Molecules that capture electrons form charged entities with a much lower mobility than the free electrons responsible for the standing current in the cell. Because of their lower mobility they lose their charge readily and hence cause a reduction in the standing current. The ECD is the only detector that measures a decrease in a large standing current; all other detectors measure an increase in a small standing current. Since the standing current can only be reduced to zero, the ECD can be easily overloaded and has, even in its modern versions, a relatively limited linear range of about 10^4 . Modern versions of the ECD pulse the voltage on the electrodes rather than using a steady DC potential. This allows equilibrium to be achieved between the electron flux and the gas mixture in the cell and is somewhat analogous to a distillation column under total reflux from which a small grab sample is removed from time to time. By changing the frequency of the pulses the current in the cell can be kept constant and the variation in frequency required to maintain a constant current is monitored rather than changes in the current itself. This is a very

simple arrangement electronically that is readily compatible with integrating circuits. The most recent modification to the ECD dispenses with the radioactive source and uses electrons produced by a helium discharge in an extension to the cell proper.

As indicated in the introduction to this section, the very high sensitivity of the ECD to polyhalogenated compounds made it extremely important for the analysis of trace pesticides in crops since many pesticides were compounds of this type. In addition to a very high sensitivity for some classes of compounds it has a negligible response for others such as paraffin hydrocarbons. Table 2 shows that the response to different classes of compounds varies over a range of at least 10^6 .

This response is not amenable to accurate prediction from the chemical structure of the compounds and even apparently small differences in structure can result in large differences in electron affinity. The ECD is not suitable for detection of an unknown mixture since large peaks may be from small amounts of compounds with high electron affinity or large amounts of compounds with a low electron affinity. In spite of its rather anomalous response and limited linear range, the ECD is an extremely important detector under favourable circumstances.

The Photoionization Detector (PID)

In the photoionization detector energy sufficient to ionize the compounds emerging from the GC is

Table 2 The electron absorption coefficients of various compounds and of classes of compound for thermal electrons

<i>Electron absorption coefficient^a</i>	<i>Compounds and classes</i>	<i>Electrophores</i>
1	Aliphatic saturated, ethenoid, ethinoid and diene hydrocarbons, benzene, and cyclopentadiene	None

supplied by a small, cheap UV lamp which can be changed over a range of wavelengths to give a certain amount of selectivity. The first commercial detector was designed to operate with packed columns but the large amount of stationary phase bleed from these columns caused rapid fouling of the quartz window of the cell facing the UV lamp and consequent deterioration of performance. Relatively simple design modifications reduced the dead volume to about 40 μL which is adequate for capillary columns of about 0.25 mm i.d. or greater. Use of capillary columns minimizes the fouling from stationary phase and also results in much sharper peaks; since the PID is a concentration-dependent detector this gives a considerable improvement in sensitivity. The main drawback of the commercial PID lies in the UV lamp sources available. Only one gives a single pure wavelength and this is of such low intensity that it offers poor sensitivity. The 10.2 eV lamp emits two wavelengths with an average energy of 10.2 eV. The inhomogeneity of the source blurs the selectivity of the detector although there is no doubt that it gives up to two orders of magnitude greater sensitivity for aromatics over aliphatic compounds with olefins somewhere in between. The lamp of higher wavelength (11.7 eV) is sufficiently energetic to ionize most compounds indiscriminately so the detector fitted with this lamp becomes more or less universal in response. The ideal version of this detector would be one with a tunable laser source and such a detector might rival the mass spectrometer in qualitative information. Unfortunately, the current cost of a tunable laser would render the detector prohibitively expensive and development on these lines is unlikely in the near future.

The FTIR Detector

The main disadvantage of simple mass spectrometry detection is its inability to distinguish between many positional isomers. The technique ideally suited to give such information and the presence of functional groups such as CO and OH is IR spectroscopy. Conventional IR spectroscopy with a grating is too slow for GC purposes but FTIR has the required speed provided that sufficient computing power is available (the computing power required is considerably greater than that required for other techniques). Another disadvantage is that the spectra obtained are gas phase spectra whereas IR spectral libraries have been traditionally liquid phase spectra. The main disadvantages, however, are the wide variation in extinction coefficients, the rather poor sensitivity for many compounds (the upper nanogram range) and light pipe cells with a relatively large dead volume.

Since capillary GC seems to be moving in the direction of faster separations via short, very narrow bore capillaries it seems doubtful if GC-FTIR will ever find any great application except perhaps in niche application areas such as essential oil and perfumery analysis.

Conclusion

There still appears to be a place for selective detectors provided that they can offer specific advantages. Early versions of most of the detectors described appeared 30 or more years ago and have survived by constant modifications and improvement in design and performance. In the light of this and the fact that just about every conceivable property of gas mixtures has been exploited over the years it is difficult to envisage any great new advance.

Many detectors have specific advantages for particular applications. The PID only requires one gas supply which makes it suitable for portable equipment. A laboratory monitoring the amount of stenching agents in natural gas is hardly likely to abandon the simplest form of FPD for anything more sophisticated. The ECD reigns supreme in the field of polyhalogenated compounds and the O-FID is ideally suited for the purpose that it was designed for. As speed of analysis increases, detectors are required with very fast response time and low dead volume leading to devices such as time-of-flight mass spectrometers. It would appear that in spite of nearly 50 years of continuous development there is still room for further advances in detectors.

Knowing the identity of each component in a mixture is necessary for many analytical-scale separations, and simply measuring retention data for this purpose is often too ambiguous for the identification of molecules eluting from a capillary gas chromatography (GC) column, which has the capability of resolving several hundred components. Prior knowledge about the chemical structure of the components and spiking of the mixture with one or more reference standards may aid the identification process; however, a less ambiguous identification can be accomplished by interfacing the chromatograph to a sensitive, rapid-scanning spectrometer to obtain unique signatures of each component. This instrument should allow each component to be detected in real time without any loss in chromatographic resolution. Mass spectrometry (MS) is the most commonly applied technique for this purpose, but it has certain limitations, in particular for distinguishing between structural isomers, such as *ortho*-, *meta*- and *para*-xylene, whose electron-impact and chemical-ionization mass spectra are identical. For such molecules a technique complementary to MS is desired. Fourier transform infrared (FT-IR) spectrometry, which yields unique spectra for most structural isomers, has frequently been used as an alternative technique for this purpose.

Light-Pipe-Based GC-IR Instruments

Measurement of the Spectrum

The coupling of gas chromatographs and FT-IR spectrometers (GC-IR) has been accomplished by three approaches. In the first, and by far the simplest, the

GC column is connected directly to a heated flow-through cell. For capillary GC, this cell is usually fabricated from a 10-cm length of heated glass tubing with an internal diameter of ~ 1 mm. The inside bore of this tube is coated with a thick enough film of gold to be highly reflective to infrared (IR) radiation. IR-transparent windows (for example made of potassium bromide) are attached to both ends of the tube. IR radiation entering one window is multiply reflected down the gold-coated interior bore before emerging from the other window, giving rise to the name *light-pipe* for this device. The effluent from the GC column is passed into one end of the tube and out of the other via heated fused-silica transfer lines. The entire unit is held at a temperature between 250 and 300°C to preclude the condensation of semi-volatile materials.

Infrared radiation from an incandescent source, such as an SiC Globar, is collimated and passed through a rapid-scanning interferometer so that each wavelength in the spectrum is modulated at a different frequency. The beam of radiation is then focused onto the first window of the light-pipe and the infrared beam emerging from the second window is refocused onto a sensitive detector (typically a liquid-nitrogen-cooled mercury cadmium telluride (MCT) photoconductive detector). A typical system is illustrated schematically in **Figure 1**. The signal measured in this way is known as an *interferogram* and the Fourier transform of the interferogram yields a single-beam spectrum. By calculating the ratio of a single-beam spectrum measured when a component is present in the light-pipe to one measured when only the helium carrier gas is present, the transmittance spectrum, $T(\nu)$, of the component is obtained. The transmittance spectrum is usually immediately converted to an absorbance spectrum, $A(\nu)$, by the standard Beer's law operation, $A(\nu) = -\log_{10} T(\nu)$, as the relative intensities of bands in absorbance spectra are independent of the concentration of the analyte, thereby allowing spectral library searching to be

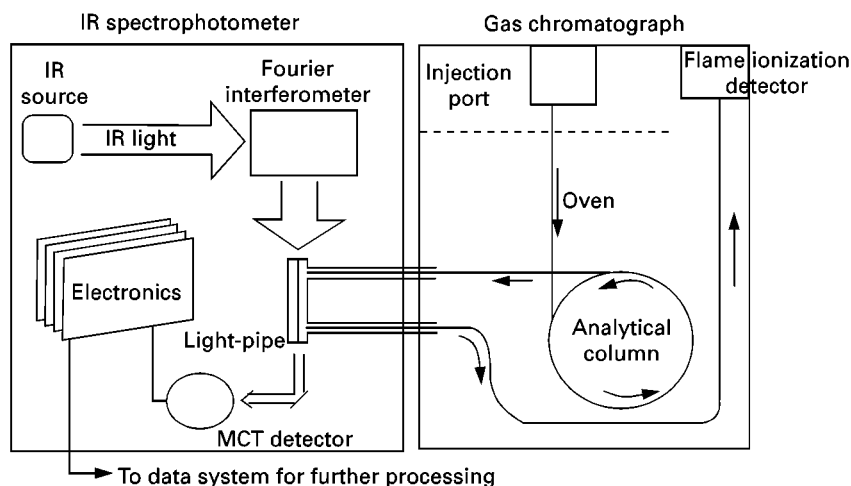

Figure 1 Schematic of typical light-pipe-based GC-FTIR interface (based on Hewlett Packard IRD).

performed. For light-pipe-based GC-IR systems, it is rarely necessary to measure spectra at high resolution, as the spectral bands are quite broad. Since most bands in the spectra of molecules in the vapour phase have a width of at least 10-cm^{-1} , the typical resolution at which GC-IR spectra are measured is 8 cm^{-1} .

When operated at their highest scan speeds, FT-IR spectrometers can measure between 5 and 20 interferograms per second that would yield spectra of this resolution. During a chromatographic analysis, interferograms are measured continuously. Thus for a 30-min-long chromatogram, it would be possible to measure tens of thousands of interferograms, giving rise to an amount of data that could exceed 100/MB and hence could exceed the capacity of the disk on a typical personal computer (PC). Fortunately, most GC peaks have a full-width at half-height (FWHH) of several seconds. Thus it is common practice to average blocks of interferograms for a period of time that is slightly less than the FWHH of the narrowest peak in the chromatogram (usually 1–2 s). The single-beam spectrum is then computed from this signal-averaged interferogram and ratioed against an appropriate background spectrum; finally, the resulting transmittance spectrum is converted to a linear absorbance format. On many fast PCs this entire sequence of operations is performed while the next block of interferograms is being acquired.

Reconstruction of Chromatograms

The end result of this process is that over 1000 absorbance spectra, corresponding to the contents of the light-pipe measured at approximately 1-s intervals throughout the entire chromatogram, are stored at the end of the run. Many of these spectra contain no useful information as they were measured when

no component was present in the light-pipe; thus the next step in a GC-IR analysis is to determine which of the stored spectra contain useful information. To achieve this, a chromatogram must be reconstructed from the spectroscopic data. This is usually achieved in two ways, the first of which is known as the *Gram-Schmidt* (GS) vector orthogonalization method. Here, short, information-rich regions of the interferograms are treated as vectors and the vector distance between this part of each interferogram measured during the chromatographic run and several interferograms that were acquired when nothing except the helium carrier gas was flowing through the light-pipe (known as the basis set) is calculated. When an analyte elutes from the column, the magnitude of the vector difference is approximately proportional to the quantity of this material in the light-pipe. Because only a short region of the interferogram is examined, calculation of the GS 'signal' can be achieved in a few milliseconds. Furthermore, since all compounds besides monatomic and homonuclear diatomic molecules have at least one band in their IR spectrum, GS chromatograms are very nonselective. Some compounds yield much stronger IR spectra than others, however. For example, the spectra of most nonpolar compounds are rather weak, whereas the spectra of very polar compounds are usually much stronger. As an example, the detection limits for GS chromatograms of polycyclic aromatic hydrocarbons (which have very low absorptivities over most of their IR spectra) are about 20 times greater than the corresponding values for the barbiturates (which are very polar and have several strong IR absorption bands in their spectra).

The other commonly used algorithm by which chromatograms are constructed from the IR data involves calculating the integrated absorbance in one

or more specified spectral regions. These regions are usually chosen to correspond to the characteristic absorption frequencies of functional groups present in the class(es) of molecules of interest. The chromatograms generated by this approach have been called by a variety of names including ChemigramsTM, functional group (FG) chromatograms and selective wavelength (SW) chromatograms. FG chromatograms are, of course, far more selective than GS chromatograms, but are rarely completely selective as many molecules have weak overtone and combination bands over much of the fingerprint region of the spectrum. For compounds with functional groups giving rise to intense absorption bands, such as the C=O stretching mode of carbonyl compounds, the limits of detection of FG chromatograms may be less than those of the corresponding GS chromatograms, but the two algorithms often have comparable sensitivity. A useful way to detect the presence of a particular functional group is to compare the relative heights of peaks in the GS and FG chromatograms. If the ratio of the peak heights in the FG and GS chromatograms is large, the presence of that functional group in that component is indicated: if the ratio is small, there is a much smaller probability that the analyte contains that functional group.

Spectral Searching

Once the chromatography has been completed, the spectra of those components of interest can be displayed. (In fact, several GC-IR software packages allow the spectra to be displayed while data acquisition is still in progress.) Each component generating a peak in the GS chromatogram with a signal-to-noise ratio greater than about 10 can usually be identified by comparing its spectrum to a library of vapour-phase reference spectra. The unknown and reference spectra are first scaled so that the most intense band in each spectrum has the same absorbance (usually 1.0). By treating the spectra as vectors, the Euclidean distance between the unknown and each reference spectrum is calculated. This distance is usually called the *hit quality index* (HQI); the smaller the HQI, the better is the spectral match. The highest probability for the identity of the unknown is that of the compound in the reference library yielding the smallest HQI. Some software scales the Euclidean distance and then subtracts it from, say, 1000 to give the HQI; in this case, of course, the larger the HQI, the better the spectral match. However unequivocal identifications cannot be made on this basis alone, for several reasons. The reference spectrum of the authentic analyte may not be present in the spectral library. If the spectrum of the unknown is noisy, the value of the

HQI may be determined more by noise than by the true absorption spectrum. The reference spectrum may have been measured with the sample at a different temperature from the light-pipe, measured at a slightly different resolution, or computed with a different apodization function. Finally, some members of homologous series can have very similar spectra, so it is not uncommon for compounds of the same type (e.g. methacrylate esters) to give similar HQI values.

It is always recommended that the user should make a side-by-side comparison of the GC-IR spectrum and the reference spectra of the top few 'hits' to get a good idea of the probability that the structure of the top hit, or by one of the other close hits, or whether there is enough similarity between the GC-IR spectrum and all of the closely matching reference spectra that unequivocal identification is impossible. In this case, the simultaneous application of MS may be necessary to yield an unequivocal identification.

Limits of Detection and Identification

The limit of detection (LOD) for an acceptable GC-IR response for most compounds is between about 1 and 20 ng (injected) per component, the actual value depending on the chemical nature of the analyte. The LOD is often defined with respect to the strongest band in the spectrum. Most bands in the IR spectra of nonpolar compounds are fairly weak and so these compounds tend to have the highest LODs, but even these compounds usually have at least one band in the spectrum with a high absorptivity. Examples include the C-H stretching bands of alkanes and the aromatic C-H out-of-plane deformation bands of polycyclic aromatic hydrocarbons. Detection limits also depend on the width of the GC peak; the wider the peak, the more dilute the analyte and the higher the LOD.

The amount of a given component that must be injected into the chromatograph to yield an identifiable spectrum, often known as the minimum identifiable quantity (MIQ), depends not on the *strongest* band, but on the signal-to-noise ratio of the *most characteristic bands* in the spectrum. For an analyte with a spectrum that is very different from any other spectra in the reference database, the MIQ may be only slightly higher than the LOD. On the other hand, there are often only very subtle differences between the spectra of members of this class of compounds. If the analyte is a member of a homologous series and several reference spectra of members of this series are contained in the library, the signal-to-noise ratio of the spectrum must be high, and hence the MIQ will be much greater than the LOD if the analyte is to be correctly identified.

If a minor peak is present in a chromatogram measured with a conventional GC detector such as a flame ionization detector (FID), but is not observable in the GS or FG chromatogram, it may be possible simply to inject a greater volume of the sample into the chromatograph. Even if the major components overload GC column in this case, the minor components will not. However, sometimes the major peaks will broaden to the point that they start to overlap a neighbouring minor peak. In this case, it may become necessary to subtract the spectrum of the major peak (linear in absorbance) from the spectrum measured in the region of the minor peak, to identify the minor component. This procedure is needed because of the relatively low sensitivity of light-pipe-based GC-IR instruments. Two other approaches that have led to increased sensitivity for GC-IR measurements are described here.

Matrix-Isolation GC-IR

In the first approach, argon is mixed with the helium mobile phase, either as a minor ($\sim 1\%$) component in the carrier gas or by addition at the end of the GC column. The column effluent is then sprayed from a heated fused-silica transfer line onto a rotating gold-plated disk that is maintained at a temperature of less than 15 K. Helium does not condense at this temperature but argon does. By locating the end of the transfer line an appropriate distance from the cooled disk, argon is deposited as a track approximately 300 μm in width. Any component emerging from the transfer line at the same time is trapped in the argon matrix. After the separation has been completed, the disk is rotated to a position where the focused beam from an FT-IR spectrometer is transmitted through the track of argon, reflects from the gold-coated disk, passes again through the argon and then is collected and focused on to an MCT detector, as shown in **Figure 2**. In principle, if the concentration of any analyte in the argon matrix is low enough, each analyte in the argon matrix is low enough, each analyte molecule will be isolated from similar molecules by the argon matrix. Despite the fact that the concentration is usually a little too high for true matrix isolation to be achieved in GC-IR measurements, this technique none the less is known as *matrix-isolation GC-IR*. By rotating the disk slowly, a series of spectra can be measured that is analogous to the series of spectra that is measured in real-time during a light-pipe-based GC-IR run and either GS or FG chromatograms can be constructed from these data. Each component may be identified by spectral library searching, but a special library of spectra of matrix-isolated standards is required.

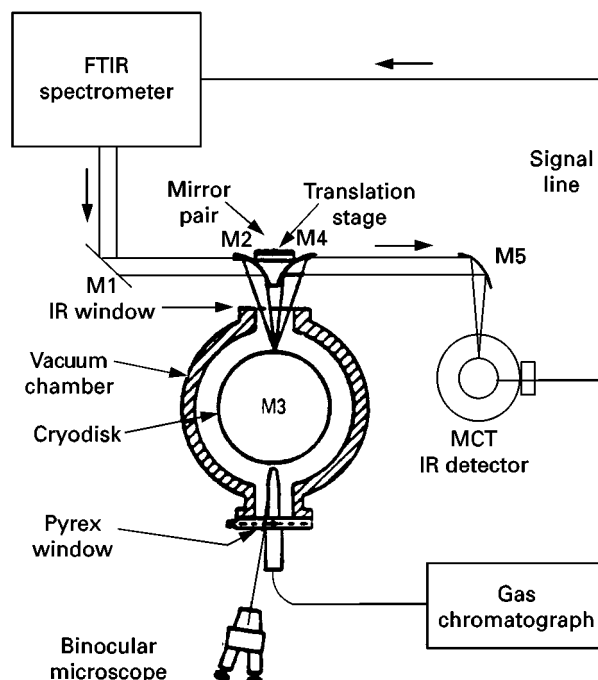

Figure 2 Schematic diagram of matrix-isolation GC-FTIR interface (based on Mattson Instruments Cryolect).

The advantages of matrix isolation are based on the following considerations. First, the width of the track is about 300 μm , compared with 1 mm for the diameter of a light-pipe. Thus the sample is more concentrated over the cross-sectional area of the IR beam and a given amount of sample will yield a spectrum with more intense absorption bands. Second, because each component is trapped on the disk, it is common practice when minor components are to be identified by matrix isolation GC-IR to signal-average interferograms for several minutes with the disk stationary, enabling a significant increase in sensitivity to be achieved over real-time measurements. A final advantage that has been claimed for matrix-isolation GC-IR measurements is the increase in the absorptivity at the peak of each band in the spectrum because of the decrease in bandwidth that occurs on matrix isolation (the band area remaining approximately constant). This is true for small molecules, but large molecules disrupt the crystal structure of the argon to such an extent that a certain amount of molecular motion is possible. As a result, the widths of many bands in the spectra of large asymmetric molecules prepared in this way are surprisingly similar to widths of corresponding bands in the spectra of the corresponding molecules prepared as KBr disks.

The exception to this behaviour is observed in the spectra of compounds that contain O-H or N-H groups. In the crystalline form of such compounds,

the O–H and N–H groups are strongly intermolecularly hydrogen bonded. As a consequence, the O–H and N–H stretching bands in their KBr-disk spectra are exceptionally broad, often having a width of several hundred wavenumbers. When these molecules are isolated in an argon matrix, however, no intermolecular hydrogen bonding takes place, and the O–H and N–H stretching bands appear as very narrow spectral features. Thus, when the spectra of matrix-isolated species such as alcohols, phenols or amines are measured at high resolution, excellent specificity is often gained by matrix-isolation GC-IR.

The major problem with this approach to GC-IR (which can to a certain extent be shared with vapour-phase measurements) is the lack of extensive libraries of appropriate reference spectra. This disadvantage has largely been overcome by the final type of GC-IR interface, which is described next.

Direct-Deposition GC-IR

In the remaining approach to GC-IR, the effluent from the column is directed at a slowly moving, cooled window mounted on a computer-controlled x - y stage. Zinc selenide cooled to the temperature of liquid nitrogen is the most commonly used substrate. Each eluting component is deposited on the window as a very narrow spot. In the commercially available form of this interface, shown in Figure 3, the typical width of each spot is about 100 μm . The stage moves so that each deposited component passes through the beam focus of an IR microspectrometer shortly after deposition. As for light-pipe-based GC-IR systems, spectra are measured continuously throughout the chromatographic run and GS and/or FG chromatograms can be output in real time. This *direct depos-*

ition approach for GC-IR has two important advantages over light-pipe or matrix isolation GC-IR systems – it yields higher sensitivity and the measured spectra are very similar to reference spectra of standards prepared as KBr disks. Let us first recognize the reason for the increased sensitivity of direct deposition GC-IR measurements.

As we saw in the previous section, the smaller the cross-sectional area of the sample, the greater the absorbance of all bands in the spectrum. Because the sample is contained in a 100- μm diameter spot rather than a 1-mm diameter light-pipe, its cross-sectional area is 100 times less, so that bands will be about 100 times more intense. To attain the optimal sensitivity, the diameter of the IR beam should be approximately equal to the width of the spot, i.e. about 100 μm , and a detector of the same size should also be used. Several other optical factors should be included in the comparison, but in general it is found that the signal-to-noise ratio of GC-IR spectra measured online using the direct deposition technique is about 50 times greater than the corresponding measurement made using a light-pipe system. The sensitivity advantage of direct-deposition GC-IR systems can be further increased by post-run signal averaging in a manner analogous to the matrix-isolation GC-IR system described previously. If each real-time spectrum is measured over 1-s blocks, post-run averaging for just 1 min will yield an improvement in sensitivity of almost a factor of eight.

As noted previously, the MIQ or direct-deposition GC-IR measurements varies with the polarity of the analyte. The LOD for real-time measurements of several analytes by this technique is about 50 pg. When very polar analytes are injected, this number can be further reduced. For example, the LOD for several barbiturates is found to be about 13 pg. Spectra of these barbiturates in the high-wavenumber region measured by a light-pipe-based GC-IR instrument (Hewlett Packard IRD) and a direct-deposition system (Bio-Rad/Digilab Tracer) are shown in Figure 4. Differences between the vapour-phase and condensed-phase spectra of molecules that can exhibit strong intermolecular hydrogen bonding are readily apparent in this figure. For example, the sharp bands absorbing near 3430 cm^{-1} in the vapour-phase spectra are due to the N–H stretching vibrations of isolated (non-hydrogen-bonded) molecules. In the corresponding condensed-phase spectra measured by direct deposition GC-IR, the N–H stretching modes of the intermolecularly hydrogen-bonded barbiturates are seen as broad bands near 3220 and 3110 cm^{-1} . Similar differences between vapour-phase and condensed-phase spectra of barbiturates are also seen in the spectral region between 2000 and 1000 cm^{-1} (see

Figure 3 Schematic diagram of direct deposition GC-FTIR interface (based on Bio-Rad/Digilab Tracer).

Figure 4 (A) Flow-cell and (B) direct-deposition GC-FTIR spectra of (a) barbital, (b) aprobarbital, (c) butabarbital and (d) phenobarbital from 4000 to 2500 cm^{-1} ; 12.5 ng and 375 pg of each component were injected for the light-pipe and direct-deposition spectra, respectively.

Figure 5). The difference between the sensitivity of the light-pipe and direct-deposition GC-IR measurements can be seen by comparing the noise levels of the spectra shown in Figure 4 and recognizing that it required 30 times more of each barbiturate to be injected for the spectra measured using a light-pipe than for those measured using direct deposition.

On deposition, the molecules of a given analyte form randomly oriented crystallites on the zinc selenide window. These crystallites are similar to the crystallites that are formed on grinding of solid samples during the preparation of KBr disks or mineral-oil mulls. Not surprisingly, therefore, the spectra of compounds obtained by direct-deposition GC-IR are

Figure 5 Low-wavenumber region of the spectra shown in Figure 4.

very similar to the KBr-disk spectra of the corresponding compounds. Extensive libraries (>150 000 entries) of reference spectra of standards prepared in this way are available commercially. The only compounds that cannot be readily identified in this manner are molecules with very strongly hydrogen-bonding groups or for analytes exhibiting polymorphism. For trace analytes containing O-H or N-H groups, the best results on library searching are usually found by examining only the spectral region below 2000 cm^{-1} and eliminating the region containing the strong, broad O-H and N-H stretching modes from the search.

Prognostication

Online IR spectrometry is proving to be an important way of identifying molecules eluting from a gas chromatograph. Light-pipe-based systems are the simplest, least expensive and most reliable, but often prove to have inadequate sensitivity for the identification of minor components. Of the two deposition-based techniques, the direct-deposition approach has LODs that rival those of benchtop GC-MS systems and has the great advantage of producing spectra that are directly comparable with KBr-disk reference spectra, of which there are over 150 000 available in digital form (i.e. suitable for computerized library searching). Thus one can forecast an increasing use of systems based on this principle in the future. It is also noteworthy that interfaces between FT-IR spectro-

meters and both supercritical-fluid and liquid chromatographs based on the same principle have been described.

During recent decades much interest has been focused on hyphenated analytical techniques. Gas chromatography (GC), liquid chromatography (LC), mass spectrometry (MS) and Fourier transform infrared (FTIR) spectrophotometry have been arranged online, usually in a series. For example a GC separation directly combined with IR or MS is established and

widespread. The combination considerably increases the degree of selectivity and identification possibilities. This is also applicable for ultraviolet (UV) absorption spectrophotometry, but GC-UV has been largely overlooked. The interest concerning UV absorption spectrophotometry for analytical purposes has been directed towards the liquid phase for the vast majority of studies involving UV absorption because of its frequent use as a detector for high performance liquid chromatography (HPLC).

However, the first attempt to utilize UV absorption detection combined with GC was made by Kaye in

the early 1960s. He used a Beckman DK2 spectrophotometer and, in order to reach the far UV region, the instrument was purged by nitrogen. He recorded spectra of various substances in the vapour phase by means of a high speed mechanical scanner and a fast recorder in the wavelength range of 165–220 nm. His article from 1961 concerning analytical applications of UV spectroscopy includes a list of 256 references. The oldest reference was from 1932, but the first analytical application of UV absorption in the gas phase, which reported the determination of ammonia in nitrogen and in air, was from 1956.

At that time there were highly limited possibilities for handling large numbers of full scan data. Interest during this period was also increasingly focused on GC-MS and later also on GC-FTIR. These circumstances probably led to the lack of interest concerning the GC-UV hyphenation for a long time. Novotny published work on GC-UV in 1980 in connection with the introduction of Perkin Elmer GC-55 UV detector. The detection was carried out at various single wavelengths. This instrument was, for some reasons, withdrawn from the market shortly afterwards.

From about the mid-1980s there has been a gradual increase in interest in GC-UV. Most of the instrumental techniques described use commercially available spectrophotometers working in either a direct or remote configuration. With these conventional instruments there is no possibility of measuring at wavelengths shorter than 190 nm. A new instrument, GC-UV INSCAN 175 spectrophotometer, was introduced on the market in 1996. This instrument has been used for spectral recordings of reference substances and a spectral library of about 1000 gas-phase UV spectra in the wavelength region of 168–330 nm has been established for the first time.

Tables 1 and 2 present the development of GC-UV in terms of the spectrophotometric and chromatographic conditions and specifications found in the literature. The various subjects discussed in these works are, for example, the influence of temperature on the noise level and the signal-to-noise ratios at various wavelengths. A number of examples of analysis, applications and determinations of isomers have been published. No review articles or monographs have yet been written about GC-UV. However, there is a thesis, mainly dealing with this subject and its development until 1992, and a popular science article was published in 1996 (see Further Reading).

Gas-phase UV Spectrophotometry

The spectral region of the UV electromagnetic absorption of interest to the analytical chemists extends from about 160 to 330 nm. Molecules in which all

valence shell electrons are involved in single bonds, such as the straight chain saturated hydrocarbons, show absorption maxima in the region of 160–170 nm. Their spectra are observed only as ‘end absorptions’ because of instrumental limitations. The other groups of nonaromatic hydrocarbons are bathochromic-shifted and possess their absorption edges in the range of 190–200 nm. This is one aspect of the importance of measuring the absorption of the UV light in the gas phase because there is no solvent wavelength cutoff at 190–200 nm. The other important aspect is that the spectra are not influenced by solvent effects and therefore well defined. There are also no shifts in λ_{\max} values and the bands are sharp in comparison with the relatively broad bands observed in the liquid phase, where their shapes depend on the degree of interaction between solvent and solute. Furthermore, in liquids, it is only very rarely that separation of vibrational bands is possible because the solvent effect generally tends to obscure the vibrational structure. By measurements in the vapour phase, these drawbacks are eliminated, which makes the UV spectra in the gas phase highly suitable for computer-based identifications of unknowns against a spectrum reference library. An example of the reproducibility of spectral details is shown in Figure 1, where a spectrum, taken from an analysis of cigarette smoke, is normalized and overlaid on the reference spectrum of isoprene. The absorbance spectra as well as the first derivatives are plotted. Derivatives of absorption spectra are preferably used in order to enhance spectral details. Derivatives of spectra can also be utilized in order to make selective determination of specific functional groups.

A study of molecular UV absorption spectra between 168–330 nm in the gas phase, for about 1000 organic compounds has demonstrated the importance of the short UV wavelengths for analytical purposes. About 70% of the 1000 spectra registered have absorption maxima at wavelengths shorter than 190 nm and their intensities are up to 100 times higher than those of the absorption bands at longer wavelengths. In addition to the high sensitivity of detection, the lower wavelength region is the spectral range, where the amount of details used for identification purposes increases considerably. Moreover, most of the functional groups in compounds not considered UV-absorbing, such as alkanes, ethers, aldehydes and ketones, display detailed spectra in this region.

The influence of temperature on the shape of spectra has been studied in the range of 15–205°C. A slight broadening effect on spectral absorption bands (0.3 nm) and the vibrational structure (maximally 1.4 nm) with increased temperature was observed. These effects are however, considered to have

negligible influence on spectral searching for unknowns, especially if the reference spectrum and the unknown spectrum are registered at similar temperatures.

Instrumentation

The various parts of a GC-UV instrumental set-up are shown in Figure 2. This particular equipment consists of a remote configuration between the gas flow cell and a commercially available UV spectrophotometer (LC detector). For this arrangement fibre-optics were utilized.

The only commercial instrument, the GC-UV INSCAN 175 spectrophotometer, contains a purge gas flow system, which takes up the concept from Keye, in order to prevent oxygen and water vapour from entering the UV light path of the instrument. Nitro-

gen gas has a negligible absorption at wavelengths longer than 140 nm. Therefore dry and pure nitrogen can be used as the purge gas, which permits recordings at wavelengths shorter than 190 nm, which is the limit if air is present in the optical path. The lowest limit of the spectral scale (168 nm) is dependent on the quartz optics and the diode array. The additional available wavelength range of 168–190 nm is of considerable importance for the performance characteristics of the instrument. It places the GC-UV into a general method of analysis because all organic compounds and most of the inorganic gaseous molecules give rise to detailed spectra of high intensities in this range.

Light Pipes

From Table 1 it can be seen that the geometry of the gas flow cells used differs considerably, with path

Figure 1 The reference spectrum for isoprene and a spectrum recorded at the analysis of 200 μL cigarette smoke. Both absorption spectra are normalized and overlaid together with their first derivatives. —, Unknown absorbance; --, reference absorbance;, unknown dA ;, reference dA .

lengths varying from 1 cm up to 12.5 cm and volumes ranging from 70 μL up to 22 mL. Optimization of the gas flow cell involves keeping a low volume for a good chromatographic resolution. At the same time, the path length and the light throughput should be maximized. These optimization factors are the same as for GC-FTIR, where an internally gold-coated gas flow cell is used. A total reflection is obtained at the gold-coated walls, leading to a high light throughput in gas flow cells about 10 cm long and with an internal diameter usually ~ 1 mm. Because of the use of internal reflection, these gas flow cells are called light pipes. For GC-UV it was realized, at an early stage, that an internal coating was not necessary and an ordinary glass tubing gave a high light throughput due to a total reflection of UV light on the internal glass walls.

A useful rule is that the optimum performance of a GC-UV system in terms of signal-to-noise and band dispersion is obtained from a light pipe with an effective volume equivalent to the volume of a 'typical' GC peak, described by the peak width at half the maximum amplitude. Typical light pipe volumes currently employed for GC-FTIR vary from 50 to 200 μL and these figures should also be valid for GC-UV light pipes.

Figure 3 shows a light pipe configuration that consists of a gas flow cell with a built in micro gas chromatograph together with the light pipe. In addition to the use of this internal micro GC, the cell can easily be linked to an external capillary GC by means of a heated transfer line, as shown in the figure. The 10 cm long gas chromatographic column, which can also be directly connected to a one-stage thermal

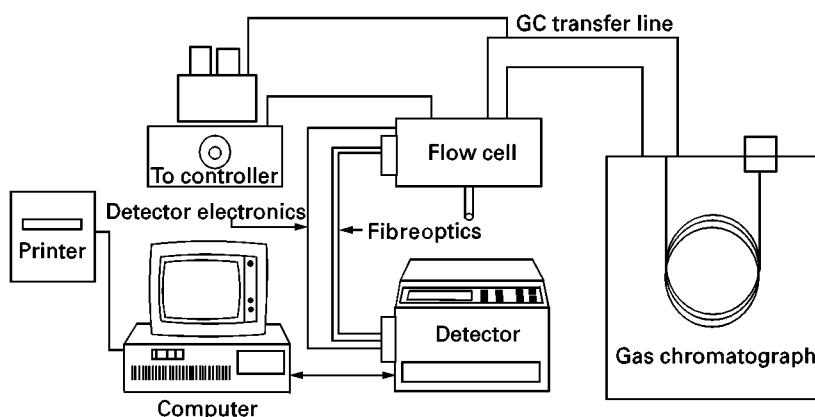

Figure 2 Block diagram for a GC-UV system. Reproduced from (1992) *Capillary gas chromatography. Rev. Sci. Instrum.* 63(1): 192.

desorption unit or to a gas loop injector, is preferably used for fast separations of gaseous and relatively volatile molecules.

Spectrophotometric Detection and Recording

Earlier work involved measurements at a single wavelength while recent spectrophotometric detection involves full spectral scans covering the whole chromatographic retention time scale. The results are obtained in three dimensions – wavelength, absorbance and retention time. Such a result is shown in **Figure 4**, where the wavelength scale follows the x -axis, the absorbance values the y -axis and the retention time goes along the z -axis. This particular sample is cigarette smoke injected by means of a loop injector (200 μL) on the micro gas chromatograph shown in **Figure 3**. UV spectra of compounds in the cigarette smoke are measured by means of an array of 1024 diodes, which cover a wavelength range from 168 to 330 nm. The spectrometer employed has a band width 1.7 nm or less in order to record the finer spectral details. The diode array detectors usually have a minimum exposure time of 0.02 s. The

measuring exposure time must be below a level where a saturation of the diodes occurs. Typically, the exposure time is ~ 0.1 s. A number of these exposure values are measured and their average is calculated. The absorbance values at any retention time are then calculated for every diode representing a wavelength. The number of the exposure values are chosen according to the desirable chromatographic resolution.

Data Acquisition and Handling

A full scan GC-UV analysis generates a considerable amount of data. These data, which are calculated as absorbance values, easily exceed 10^6 measuring points, when capillary column separation with spectral recording every 2 s is employed. However, the use of modern computer technology makes the handling of a large number of measuring values possible. Various calculations and mathematical functions can be applied to the measuring data. Besides the simple functions, interactive subtraction, baseline corrections, various orders of derivatives, rotation (90°), damping functions and cuts at selected wavelengths can be applied.

Figure 3 A 10 cm long gas flow cell for GC-UV measurements containing a built-in micro gas chromatograph and a light pipe *a*, Injector; *b*, injector chamber with carrier gas inlet; *c*, separation column; *d*, inlet from external GC; *e*, light pipe.

Figure 4 Results of cigarette smoke analysis obtained with the GC-UV method with the micro gas chromatograph, which is especially suitable for analysis of the most volatile compounds in cigarette smoke. The wavelength scale follows the *x*-axis, the absorbances the *y*-axis, and retention time the *z*-axes.

During an analysis the recording follows the axes shown in Figure 4 and, in order to monitor the chromatographic sequence, the data are turned 90° to get the retention time along the *x*-axes. Chromatograms can now be studied at any chosen wavelength, or for the average absorptions within a chosen wavelength region.

The gas-phase UV spectra are well defined and most of them contain a fine structure. In order to enhance the spectral details, derivatives of the absorption spectra are preferably utilized. When forming chromatograms the negative values obtained upon derivation are not convenient to handle and, to avoid this problem, the absolute values of the derivatives can be used. **Figure 5** shows the results from an analysis of a polychlorinated biphenyl (PCB, Arochlor

1248) sample. The presentation mode of the measured values is the same as for Figure 4, but the second derivatives with absolute values of the recorded absorption spectra are drawn for the retention times between 800 and 1600 s. The spectral details of the congeners and isomers concerning this group of related compounds appear quite clearly. Various types of graphical views can be carried out in order to suit certain presentations of results. One example of such a view is a contour plot, which is an effective way to treat the results. In **Figure 6** a contour plot is created from the analysis of a petroleum product. The advantage of these type of presentations is that compounds with close retention times appear as nonsymmetrical contour lines, which makes it possible to 'see' the hidden peaks. Another advantage is that

Figure 5 The result from a retention time of 800 s up to 1600 s is shown in a three-dimensional plot of the absolute values of second derivatives of absorption spectra collected at the analysis of a PCB sample.

compounds possessing the same functional group can often be directly shown.

Accuracy and Precision

To describe a position in the absorption spectrum the wavelength is used as the locating unit. This puts a high demand on the spectrophotometric measurements, especially accuracy, precision and reproducibility, of the wavelength. The weekly calibration of the wavelength scale of GC-UV INSCAN 175 spectrophotometer, using the spectral lines from a mercury-argon pen lamp, always gave the same wavelength values of the spectral lines measured in the region of 168–330 nm. The 1024 element photodiode array covers the scale from 166.7 to 330.0 nm. This gives a value of 0.16 nm per diode, which is to be considered as an ultimate limit of resolution. The reproducibility was measured for different bands of 1-hexene (λ_{\max} 178.7 nm), 1-hexadecene (λ_{\max}

177.9 nm) and 1-iodopropane (the band at λ : 177.6 nm, at λ_{\max} : 182.7 nm and the band at λ : 199.4 nm) for 1 year. The standard deviation values were in the range of 0.05–0.15 nm, i.e. all were lower than the distance between two diodes (0.16 nm).

Sensitivity and Detection Limits

The discrepancy in sensitivity of the GC-UV method, given by detection limits in Table 2, can primarily be derived from the differences in the geometry of the gas flow cell and from the separation columns (packed or capillary) used.

In comparison with the infrared wavelength region, the absorptivities are up to 1000 times higher in the UV wavelength region. Also, the fact that the noise level could be kept equal to or lower than for FTIR detectors ought to imply a considerably more favourable signal-to-noise ratio. The specification concerning the noise level, along the time scale, given

Figure 6 A contour plot showing the result obtained at the analysis of a petroleum product: the second derivatives are plotted and, as indicated, the single, double and polyaromatic compounds appear clearly.

for the GC-UV INSCAN 175 spectrophotometer, is about 0.5×10^{-4} peak to peak.

For a detection limit defined as the amount giving rise to an absorption of 1.5×10^{-4} AU, and expressed as the minimum amount of the compound per second that could be detected, the following values were calculated: perchloroethylene 55 pg s^{-1} , naphthalene 3.3 pg s^{-1} , mesitylene 8.9 pg s^{-1} , carbon disulfide 4.8 pg s^{-1} , acetone 49 pg s^{-1} and benzene 5.4 pg s^{-1} .

The noise level can be lowered by smoothing and by taking the average absorption values within a wavelength range. However, it has been shown that this noise reduction is most effectively obtained using average derivatives values. The derivatives are in these cases differentials with a rather large gap value

(2–6 nm) along the wavelength scale. The noise level obtained, using this mode, was $\sim 1 \times 10^{-5}$ AU peak to peak, which gives a calculated detection limit for naphthalene of $\sim 0.5 \text{ pg s}^{-1}$.

The limit of quantification (MIQ: minimum identification quantity) is usually defined as the lowest quantity when the hit rate of the unknown is still found among the first five proposals. This depends on the size of the spectrum library and, at this stage, the available reference spectrum library is probably not large enough to make any closer estimations. However, clear identifications can be made in the mid pg range, provided that the compound possesses a functional group with relatively high absorptivity values (e.g. aromatics). For the GC-UV method the

introduction of an additional sensitivity level, namely a minimum of classification quantity (MCQ), appears to be desirable. The suggestion is to define MCQ as the minimum quantity necessary for giving the right functional group at the first library search proposal.

Qualitative Analysis

The identification of an unknown is commonly carried out by comparison with a library of reference gas-phase spectra. The absorption process of an atom or a molecule in the gas phase is free from any influence, which reproduces not only the unique character of the electronic transitions, but also of the accompanying simultaneous changes in the vibrational states. This gives rise to spectral shapes which are strictly defined and, in most cases, accompanied by fine structures. Therefore the UV spectra are well suited for identification by means of a computer-based spectral search against a reference spectrum library. A spectrum library of ~ 1000 gas-phase UV spectra recorded in the wavelength region of 168–330 nm has been established. A commercially available IR search program has been used with success for identification. Because of the relatively small size of this library, the identification possibilities are limited. Nevertheless, identification of classes of compounds can most often be directly pointed out. The compounds containing the same functional group show a number of characteristic similarities, but at the same time clear differences between individuals within a group are observed. The exceptions are cases when various straight alkyl chains are involved. The spectra of acetophenone and propiophenone, for example, are hard to distinguish from each other.

Determination of Specific Functional Groups

The reference spectrum library mentioned above has made it possible to identify ~ 50 functional groups due to their characteristic spectral appearances. These characteristics allow the assignment of a specific functional group in a compound without access to any reference spectrum. The specific functional groups can, for example, be exposed in a contour plot shown in Figure 6, where the measuring data (second derivatives) for single, double and polyaromatic compounds are outlined quite clearly. Specific chromatograms can be obtained for these aromatic groups by taking the average absorption in appropriate wavelength ranges.

Another example of specific detection is shown in Figure 7, where 6 mg of a dust sample was analysed by means of GC-MS and GC-UV. In both cases the analysis involved a thermal desorption before the gas chromatographic separation and in both cases the same type of capillary column and the same temper-

ature programme were used. Figure 7A shows the chromatogram from the GC-MS total ion signal and Figure 7B–D shows the GC-UV chromatograms obtained at the wavelength ranges indicated. The chromatograms were calculated using the absolute values of the first derivatives of absorption spectra. Identifications were carried out by means of GC-MS for the peaks indicated 1–5 with following results: (1) hexanal; (2) heptanal; (3) octanal, (4) nonanal and (5) decanal. The nonaromatic straight chain aldehyde group has a characteristic sharp UV absorption edge at 187 nm. Therefore a specific detection of nonaromatic straight chain aldehydes can be made in the 187–190 nm wavelength range, as shown in the figure. The next GC-UV trace shows the chromatogram from the average values in the 187–220 nm range. This gives a less specific chromatogram. Naphthalene was identified at the indicated position (6) by means of a search against the gas-phase UV reference spectra library. The same library was used for the identifications of benzaldehyde at position (7) and 2-furaldehyde at position (8). The spectrum of 2-furaldehyde has a dominating absorption profile between 230 and 270 nm and, consequently, it only appears in the 238–244 nm wavelength trace.

The experiences of combining results from GC-MS and GC-UV have recently been explored and there are indications of valuable possibilities. The characteristic complementary qualities for GC-UV compared to GC-MS allow specific determinations – determinations of specific functional groups and also of structural isomers, which are difficult to distinguish by means of MS.

Isomers

There are numerous examples of structural isomers in chemistry and isomers of a certain compound have different physical and chemical as well as physiological properties. Thus, for example in the field of toxicology, some isomers possess toxicity which differ by several orders of magnitude.

Ninety-five groups of various isomeric compounds have been investigated and in all cases the GC-UV method was able to distinguish clearly between structural isomers. However, when the analysis involves various straight or branched alkyl chains the identification is complicated. For difficult identifications like these derivative functions can be applied in order to enhance differences in spectral details and thus distinguish between isomers not resolved by comparing the absorbance spectra alone. Some groups, like nonaromatic halogenated hydrocarbons and nonaromatic alcohols, show minimal differences. Nevertheless, they are still distinguishable and the first derivatives of their spectral curves give clear shifts of ~ 2 –3 nm in the absorption maxima and minima.

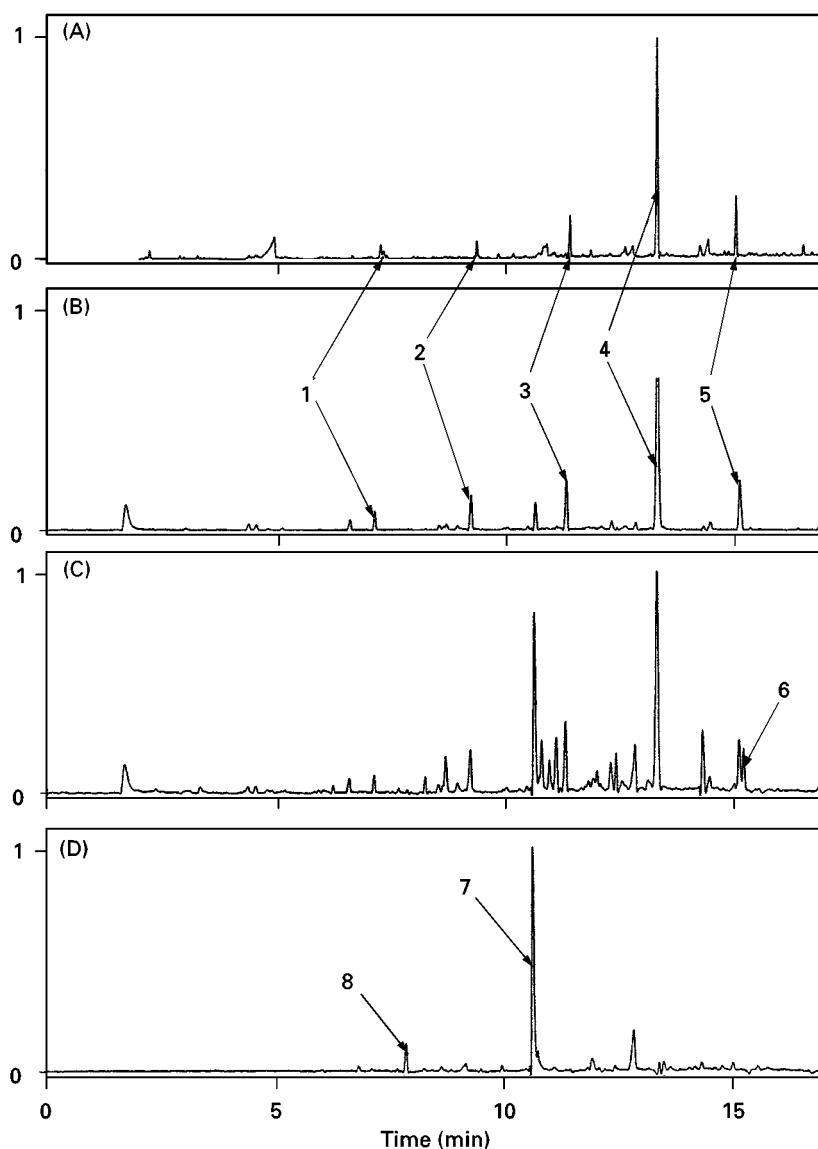

Figure 7 Four chromatograms after the analysis of a dust sample. (A) The upper trace shows the total ion current (TIC) obtained from the analysis of 10 mg dust by means of GC-MS linked to the thermal desorption unit. The next three traces show the chromatograms based on first derivatives for (B) 187–190 nm, (C) 187–220 nm and (D) 238–244 nm wavelength ranges from the analysis of 6 mg dust by means of GC-UV. The peaks indicated 1–5 were identified using GC-MS and the peaks indicated by 6–8 by GC-UV. The identification results are given in the text.

Quantitative Analysis

A linearity of detector response over a range of $\sim 10^4$ for aromatic hydrocarbons in the vapour phase has been reported. Similar linear responses were observed for more polar aromatic compounds (coumarin and phenols) and no deviations from Lambert–Beer’s law were found in the range of the mass loading limits imposed by the capillary column employed. Also the linearity for nitric oxide standards has been studied in the range of 10–1800 ng at the wavelength of 213.5 nm. The standards were prepared from a standard gas tube containing 99% nitric oxide. Standard concentrations in nitrogen were prepared

from the tube using Tedlar bags and gas-tight syringes. The standard curves were linear in the range studied.

Studies of day-to-day variation and repeatability have been carried out at a temperature of 110°C using a GC-UV INSCAN 175 spectrophotometer linked to a dynamic dilution system for the standard concentrations and a 200 μ L loop injection. The compounds determined were methanethiol and diethyl sulfide. The within-day relative standard deviations (RSD) were 2.3% ($n = 7$) for diethyl sulfide at a concentration of 82 p.p.m. and 3.0% ($n = 7$) for methanethiol at 79 p.p.m. The between-days deviations were measured for 3 months ($n = 36$). The RSD values were

determined for the slope of the standard curves, with concentrations between 80 and 2000 p.p.m.

These between-days RSD values were 4.0% for diethyl sulfide, and 5.0% for methanethiol. These results include the errors arising from the dynamic dilution system used. In this case a photo diode array type detector was employed, which has the advantage of having a low wavelength drift.

Applications

GC-UV is a general method of analysis with numerous possible application areas. So far, the method has been little used and most investigations have been concerned with the fundamentals of the analytical principle. Nevertheless, a number of works have been published, for example the determinations of nitric oxide adsorbed on mineral fibres and isoprene and acetone determinations in exhaled breath. A method, using GC-UV for the determination of alcohols, denoted as GC-GPMAS (gas chromatography with gas-phase molecular absorption spectrometry) has been reported. These are short reports concerning determinations of single, double and polyaromatics in petroleum products, volatile compounds at low concentrations in air, irritants adsorbed on dust particles, determinations of compounds present in cigarette smoke, identifications of compounds in flavour samples, analysis of methanethiol, diethyl sulfide and hydrogen sulfide in paper industry, and identifications of congenes and isomers of polychlorinated biphenyls (PCBs) and polychlorinated naphthalenes (PCNs).

Future Developments

UV absorption spectra are basically electronic spectra which arise from transitions between electronic states and are accompanied by simultaneous changes in the vibrational and rotational states. Thus, an absorption spectrum is a function of the whole structure of a molecule and an expression for its fundamental chemical properties. UV absorption spectra in the gas phase are very well defined and can be denoted as finger-

prints of organic as well as inorganic compounds. They have considerably higher absorptivities than their counterparts in the infrared wavelength region and are very well suited for computer-based spectral search systems. The size of reference spectra presently available is much smaller compared with that available for GC-FTIR and particularly for GC-MS. Future development of the GC-UV method will include continuous extension of the reference spectrum library.

One of the main advantages of UV gas-phase spectra might be to make detailed classification of functional groups. At present ~ 50 groups with characteristic features can be identified. However, this will certainly be extended and will also include a number of groups with mixed functionalities.

Concerning further instrumental development, recordings of spectra at lower wavelengths than 168 nm will probably be possible. Another instrumental development that can be expected is matrix isolation and direct deposition techniques similar to the ones developed for GC-FTIR measurements. Furthermore, the GC-UV spectrophotometer will, in the near future, be adapted to online measurements in industrial process monitoring and control.

Introduction

Gas-solid chromatography (GSC) has been used since the earliest days of gas chromatography and preceded

gas-liquid chromatography. Through this early work the limitations of GSC were well recognized and, although the advantages of GSC were also apparent, it was quite some time before reliable and reproducible GSC columns became commercially available. There are many methods in the literature describing the application of GSC to specific analyses, for example the UK Institute of Petroleum method

IP345/80 describes the use of a 3 m × 2.3 mm stainless-steel column containing Porapak R for the separation of nitrogen, oxygen and carbon dioxide and hydrocarbons up to C₈ in the gas above crude oil. The method requires programming the column from –50°C to 240°C, which is unattractive in that it requires a supply of coolant such as liquid nitrogen.

Although the superior separation characteristics of adsorption materials in porous-layer open-tubular (PLOT) columns were recognized, the main problem was that the preparation procedures for PLOT columns are complex and difficult to implement. However, with the introduction of new capillary column coating technology it is now possible to deposit stable layers of adsorbents on the inner wall of fused silica capillaries. These columns give better separations in a shorter time than the older packed columns.

Adsorption materials that are now commercially available in capillary columns are aluminium oxides, molecular sieves, activated carbon such as graphitized carbon black, porous polymers and silica. Besides fused silica capillary columns, the adsorbents are also deposited in metal columns, expanding the application of adsorbents in the area of process analysers and portable equipment.

Each adsorbent has its own specific application field, as summarized in **Table 1**. In general the application field of PLOT columns covers the permanent gases and volatile mixtures with boiling points up to c. 225°C.

Molecular Sieves

Molecular sieves are synthetic and naturally occurring zeolites with well-defined structures that have found extensive use for the separation of permanent (or fixed) gases. Molecular sieves have a pore size that is defined by the particular ion used in the preparation

of the material – calcium aluminium silicate gives a pore size of 0.5 nm, whereas sodium aluminium silicate gives a pore size of approximately 1 nm. These are the two commonest molecular sieves; other pore sizes are available but are less widely used. The separation on a molecular sieve is based on more than one retention mechanism. The first selection depends on size – molecules that are smaller than the pore size will diffuse inside the pores. Once inside the cavities, the small molecules can interact with a large surface area, which means that they will have relatively long retention times. Large molecules such as branched alkanes or sulfur hexafluoride (SF₆) are too big to enter the pores and these compounds will elute earlier. Compounds that are too large to enter the pores will only be retained by relatively weak adsorption on active sites on the outside of the particles, and thus give shorter retention times.

The retention of components with dipole interaction and hydrogen bond formation, like water and carbon dioxide, is very high. Carrier gas and samples should be as dry as possible. Water is absorbed by the molecular sieve and will cause a reduction of retention times. The water can be removed by heating for a few hours at 300°C. A molecular sieve of pore size 0.5 nm is an ideal adsorbent for the separation of permanent gases; this is also the main use of the column. Normally molecular sieves are not used for separations above C₂ except for hydrocarbon type analysis. Higher boiling compounds are strongly adsorbed and can only be eluted by using undesirably high temperatures (molecular sieves are good catalysts!), vicinal exchange coupled with backflush techniques or even destruction of the sieve with hydrogen fluoride. A typical separation of a permanent gas mixture is shown in **Figure 1**. The 0.53 mm fused silica column is usually coated with a 50 µm layer of 0.5 nm molecular sieve to generate sufficient retention to make a high resolution separation possible at temperatures above ambient. The separation of argon and oxygen is baseline. The 50 µm layer provides a relatively high retention for carbon dioxide. If the separation of argon–oxygen is not important, a 15 µm film can be used. For a comparison of the separations with 50 and 15 µm layers, see **Figures 1** and **2**. Several other applications have been reviewed. Molecular sieves are also successfully coated onto Ultimet capillary columns of 0.53 mm i.d. Applications of these columns are especially of interest for analyser systems where reliability is a major issue (see metal PLOT columns below).

Molecular sieves of the 13X type are also used. These materials have a lower absolute retention due to the larger pores. They are used in the petroleum

Table 1 General application fields of adsorbents

<i>Absorption material</i>	<i>Applications</i>
Molecular sieves	Permanent gases, hydrogen isotopes, CO, N ₂ O
Porous polymers	Volatile polar and nonpolar compounds; samples containing water; CFCs; solvents
Alumina	Hydrocarbon impurities in C ₁ –C ₅ hydrocarbons
Carbon	CO and CO ₂ in air; impurities in ethylene
Silica	C ₁ –C ₃ hydrocarbons, sulfur gases; hydrocarbon and semipolar impurities; samples containing water

CFC, chlorofluorocarbon.

Figure 1 Permanent gases on a 50 μm Molsieve 0.5 nm PLOT column. Experimental details: column, 50 m \times 0.53 mm fused silica; oven, 30°C; carrier gas, hydrogen; injection, split; detection, TCD. Peaks: 1, helium; 2, neon; 3, argon; 4, oxygen; 5, nitrogen; 6, methane.

industry for the type separation of naphthenes from paraffins, olefins, naphthenes and aromatics (PONA analysis), mainly in packed column configurations.

Figure 2 Fast separation of permanent gases on a 15 μm Molsieve 0.5 nm PLOT column. Experimental details: column, 30 m \times 0.53 mm fused silica, Molsieve 0.5 nm d_f = 15 μm ; oven, 50°C; carrier gas, hydrogen; injection, split; detection, TCD. Peaks: 1, helium + neon; 2, argon + oxygen; 3, nitrogen; 4, methane; 5, carbon monoxide.

Alumina Adsorbents

Alumina adsorbents in capillary columns were introduced as long ago as 1963 and were made commercially available in fused silica capillary columns in 1981. Alumina has a very high activity and will retain components as light as ethane. To make the highly active alumina work as stationary phase in GC, it has to be deactivated. Deactivation can be done in many ways, but the most practical and reproducible method is deactivation with inorganic salts.

Alumina deactivated with potassium chloride (KCl) provides a general nonpolar adsorbent that is widely used. Such a column will elute acetylene before butane (Figure 3). The alumina surface can be made more polar by deactivation with sodium sulfate instead of KCl. The resulting alumina layer will elute acetylene after the butane peaks, indicating the higher polarity.

The selectivity of alumina for hydrocarbons is very high. All C_1 – C_4 hydrocarbons can be baseline separated. The resolution between the different hydrocarbons is sufficient to be able to measure many trace amounts of C_1 – C_4 hydrocarbons in a main stream of any one of these hydrocarbons (Figures 4–6). For this reason alumina is one of the most widely used columns in petrochemistry for analysing hydrocarbon impurities in ethylene, propylene (Figure 5) and 1,3-butadiene (Figure 6).

Although alumina has unique separation characteristics, it also has limitations. The activity of the adsorbent is such that it will adsorb any moisture, carbon dioxide or other polar impurity in the sample. When

Figure 3 C_1 – C_6 hydrocarbons on an Al_2O_3 , KCl PLOT column. Experimental details: column, 50 m \times 0.32 mm fused silica, $\text{Al}_2\text{O}_3/\text{KCl}$, d_f = 5 μm ; oven, 70°C (4 min) \rightarrow 180°C, 10°C min^{-1} ; carrier gas, helium; injection, split; detection, flame ionization detection (FID). Peaks: 1, methane; 2, ethane; 3, ethylene; 4, propane; 5, cyclopropane; 6, propylene; 7, acetylene; 8, isobutane; 9, propadiene; 10, butane; 11, *trans*-2-butene; 12, 1-butene; 13, isobutene; 14, *cis*-2-butene; 15, isopentane; 16, methylacetylene; 17, pentane; 18, 1,3-butadiene; 19, ethylacetylene; 20, hexane.

Figure 4 Impurities in *trans*-2-butene on an $\text{Al}_2\text{O}_3/\text{Na}_2\text{SO}_4$ adsorbent PLOT column. Experimental details: column, $50\text{ m} \times 0.32\text{ mm}$ fused silica, $\text{Al}_2\text{O}_3/\text{Na}_2\text{SO}_4$, $d_f = 5\text{ }\mu\text{m}$; oven, 110°C ; carrier gas, nitrogen; injection, split; detection, FID. Peaks: 1, methane; 2, ethane; 3, ethylene; 4, propane; 5, propylene; 6, isobutane; 7, butane; 8, cyclobutane; 9, *trans*-2-butene; 10, 1-butene; 11, isobutene; 12, *cis*-2-butene; 13, 1,3-butadiene.

alumina is exposed to water, the retention times for hydrocarbons are altered and resolution is degraded. The water will deactivate the surface and, as a consequence, the column will have lower retention. The water can simply be removed and the column performance regenerated by heating to 200°C for a short time. If an isothermal setup is required, a polar pre-column that retains the water can be employed. A polyethylene glycol-coated column with a $1.2\text{ }\mu\text{m}$ film works very well as the $\text{C}_1\text{--C}_6$ hydrocarbons will elute from this column before the water and by simple backflushing or a vent switch the water peak can be removed. For more polar impurities, regeneration may take longer, but it is possible. Alumina columns are difficult to destroy and oxygen in the carrier gas will not harm the column. It has been found that sulfur impurities present up to 2000 ppm do not seriously interfere with the retention characteristics of alumina. The maximum temperature of alumina columns should not exceed 200°C ; above this temperature recrystallization of the deactivating compound will occur, causing changes in selectivity. Alumina layers coated in Ultimet tubing are very stable and find wide application in hostile environments.

Figure 5 Impurities in propylene on an $\text{Al}_2\text{O}_3/\text{KCl}$ PLOT column. Experimental details: column, $50\text{ m} \times 0.53\text{ mm}$ fused silica, $\text{Al}_2\text{O}_3/\text{KCl}$, $d_f = 10\text{ }\mu\text{m}$; oven, 40°C (10 min) $\rightarrow 160^\circ\text{C}$, 5°C min^{-1} ; carrier gas, helium; injection, split; detection, FID. Peaks: 1, methane; 2, ethane; 3, ethylene; 4, propane; 5, propylene; 6, isobutane; 7, acetylene; 8, butane; 9, propadiene; 10, *trans*-2-butene; 11, 1-butene; 12, isobutene; 13, *cis*-2-butene; 14, isopentane; 15, methylacetylene; 16, pentane; 17, 1,3-butadiene.

Porous Polymers

The preparation of capillary columns with porous polymers synthesized *in situ* was described by Hollis in 1973. These columns were quite active and only worked well for hydrocarbons; polar compounds elute with severe tailing. Using new coating techniques, it has become possible to coat porous polymers very efficiently on fused silica capillary columns.

Porous polymers are prepared by the copolymerization of styrene and divinylbenzene or other related monomers. The pore size and specific surface area can be varied by the amount of monomer added to the polymer. Several types of porous polymers have become commercially available under different names, including GS-Q, PoraPLOT Q and Supel-Q. It should be noted that the selectivity of some porous polymers in capillary columns does deviate strongly from the original polymer consisting of 100% styrene-divinylbenzene.

In general the polymer-coated capillaries are highly efficient and inert. **Figure 7** shows the separation of a range of solvents with different functional groups; all the different types of compounds elute with good peak symmetry. A typical application for a porous polymer of the 'Q' type is shown in **Figure 8**, where

Figure 6 Impurities in 1,3-butadiene on an $\text{Al}_2\text{O}_3/\text{KCl}$ PLOT column. Experimental details: column, 50 m \times 0.25 mm fused silica, $\text{Al}_2\text{O}_3/\text{KCl}$, $d_i = 4 \mu\text{m}$; oven, 50°C (1 min) \rightarrow 200°C, 10°C min $^{-1}$; carrier gas, helium; injection, split; detection, FID. Peaks: 1, methane; 2, propane; 3, propylene; 4, isobutane; 5, butane; 6, cyclobutane; 7, unknown; 8, *trans*-2-butene; 9, 1-butene; 10, isobutene; 11, *cis*-2-butene; 12, 1,3-butadiene; 13, ethylacetylene; 14, hexane.

traces of acetaldehyde are measured in a hydrocarbon matrix.

Porous polymers are also available with different selectivities. By the incorporation of vinyl pyridine or methacrylate groups, the general selectivity can be changed and the polymer can be made much more polar.

Porous polymers have become very popular because of the high retention, the inertness and the selectivity that these materials provide. With porous polymers very volatile components can be separated at temperatures above ambient. In addition, one of the unique characteristics of porous polymers is their highly hydrophobic behaviour. The interaction with

Figure 7 Solvents on a porous polymer PLOT column. Experimental details: column, 10 m \times 0.53 mm fused silica, PoraPLOT Q, $d_i = 20 \mu\text{m}$; oven, 100°C \rightarrow 200°C, 10°C min $^{-1}$; carrier gas, hydrogen; injection, split; detection, FID. Peaks: 1, methanol; 2, ethanol; 3, acetonitrile; 4, acetone; 5, isopropanol; 6, dichloromethane; 7, methylacetate; 8, pentane; 9, ethyl acetate; 10, hexane; 11, benzene.

water is very low, which results in a fast elution of water so that, for example, water elutes on a 100% styrene-divinylbenzene column before acetone and methanol.

The porous polymers are also recognized to be very inert, which makes them applicable for a wide range of compounds. A series of porous polymers of different selectivity has been commercialized and is nowadays available in 0.53, 0.32 and also 0.25 mm internal column diameter. Porous polymers have recently

Figure 8 Trace acetaldehyde in a hydrocarbon matrix. Experimental details: column, 25 m \times 0.32 mm fused silica, PoraPLOT Q, $d_i = 10 \mu\text{m}$; oven, 140°C; carrier gas, helium; injection, split; detection, mass selective detection (MSD). Peaks: 1, air, argon and methane; 2, sulfur hexafluoride; 3, ethylene; 4, ethane; 5, water; 6, propylene; 7, propane; 8, acetaldehyde; 9, isobutane; 10, butane; 11, *cis*-2-butene; 12, acetone; 13, isopentane; 14, pentane.

Figure 9 Solvents on a porous polymer PLOT column. Experimental details: column, 25 m \times 0.53 mm fused silica, PoraPLOT Q-HT, $d_i = 20 \mu\text{m}$; oven, $100^\circ\text{C} \rightarrow 250^\circ\text{C}$, 5°C min^{-1} ; carrier gas, hydrogen; injection, split; detection, FID. Peaks: 1, methanol; 2, ethanol; 3, acetonitrile; 4, acetone; 5, isopropanol; 6, dichloromethane; 7, pentane; 8, ethyl acetate; 9, hexane; 10, benzene; 11, cyclohexane; 12, toluene; 13, ethylbenzene; 14, propylbenzene; 15, decane; 16, butylbenzene; 17, undecane; 18, dodecane. Note the elution of volatile solvents.

become available in metal tubing, which has expanded their application even more as PLOT columns can now also be used in a process-type environment.

One of the latest developments is the improved stabilization of the 100% styrene-divinylbenzene porous polymers, which has resulted in the introduction of a high temperature material, called PoraPLOT Q-HT. This porous polymer can be used up to temperatures of 290°C , an increase of 40°C over the previously available material, and the bleed level of the polymer at lower temperatures has been reduced. The selectivity and inertness of the new polymer is not influenced by the stabilization process (Figure 9).

Carbon Adsorbents

Unique selectivity is found with the carbon adsorbents. This type of material has been used for many years in packed columns. One of the problems associated with the material available in the early days was its lack of reproducibility; the introduction of graphitized carbon black has improved this situation. The graphitized carbon adsorbent often has its separ-

ation properties modified by the incorporation of a small quantity of a stationary liquid such as Carbowax 20M. Two commercial materials currently available are known as Carbosieve and Carbo-pack. Much elegant work has been done on graphitized carbon black capillary columns by Bruner and his co-workers at the University of Urbino, who have demonstrated that such columns can give good separations of hydrocarbons and amines with short analysis times (see Further Reading). Their suggestion of the name GLOT (graphitized-layer open-tubular) columns has so far met with little recognition.

The Carboxene and CarboPLOT columns have comparable characteristics and are useful for the separation of carbon monoxide, carbon dioxide and air from C_1 and C_2 in coke oven gas (Figure 10). The main restriction to the application of carbon-coated PLOT columns is their limited temperature range. Carbon layers become extremely active on heating and application of these materials is limited to about

Figure 10 Coke oven gas on a carbon PLOT column. Experimental details: column, 25 m \times 0.53 mm fused silica CP-CarboPLOT P7, $d_i = 25 \mu\text{m}$; oven, $35^\circ\text{C} \rightarrow 115^\circ\text{C}$, $15^\circ\text{C min}^{-1}$; injection, split; detection, TCD/FID. Peaks: 1, hydrogen (51%); 2, oxygen (0.5%); 3, nitrogen (6%); 4, carbon monoxide (10%); 5, methane (25%); 6, carbon dioxide (2.5%); 7, ethylene (1%); 8, ethane (2%) (signal ethylene and ethane by FID).

Figure 11 Impurities in propylene on a silica PLOT column. Experimental details: column, 30 m \times 0.32 mm fused silica CP-Silica-PLOT, $d_i = 4 \mu\text{m}$; oven, $50^\circ\text{C} \rightarrow 180^\circ\text{C}$, 5°C min^{-1} ; carrier gas, helium; injection, split; detection, FID. Peaks: 1, methane; 2, ethane; 3, ethylene; 4, acetylene; 5, propane; 6, cyclopropane; 7, propylene; 8, isobutane; 9, butane; 10, 1-butene; 11, methylacetylene; 12, 1,3-butadiene; 13, *trans*-2-butene; 14, isobutene; 15, *cis*-2-butene.

200°C . Higher temperatures may be possible but require specifically deactivated layers, which involves a risk of altering the selectivity.

Silica

The application of silica as adsorption material was established from the very earliest days of GSC. Later publications have shown the high separation and inertness of silica in PLOT columns but absolute retention and capacity were always the limiting factors in successfully applying silica as an adsorbent for these columns. The deposition of a layer of silica in a capillary column could not compete with the high selectivity and retention provided by alumina or the inertness and retention of porous polymers. Theoretically, silica should be a very interesting adsorbent because it has a very low catalytic activity.

The silica layer in a silica PLOT column is activated at 250°C and can be used for a wide variety of compounds such as C_1 to C_8 hydrocarbons, volatile sulfur compounds and halogenated compounds in the C_1 to C_6 range. The hydrocarbon selectivity of a silica PLOT column is shown in Figure 11. Note the high separation efficiency of the C_1 – C_3 compounds. Also cyclopropane elutes before propylene, making low level quantification in propylene possible.

Sulfur compounds are well separated from hydrocarbons and there is, therefore, no risk of quenching if a flame photometric detector is used. Silica adsorbents also produce very sharp peaks for sulfur compounds, making low level measurement possible. Determination of carbonyl sulfide and hydrogen sulfide in pure propylene is possible down to low ppb levels using sulfur selective detection as shown in Figure 12. Sulfur dioxide also elutes as a sharp peak.

Figure 12 Volatile sulfur impurities in propylene on a silica PLOT column. Experimental details: column, 30 m \times 0.32 mm fused silica CP-SilicaPLOT, $d_i = 4 \mu\text{m}$; oven, $50^\circ\text{C} \rightarrow 120^\circ\text{C}$, $10^\circ\text{C min}^{-1}$; carrier gas, helium; injection, valve, $375 \mu\text{L}$ propylene; detection, sulfur chemiluminescence detection. Chromatogram (A): oven, 35°C, 12 min \rightarrow 150°C, 4°C min $^{-1}$; carrier gas, helium, 2.5 mL min $^{-1}$. Chromatogram (B): oven, 70°C, 12 min \rightarrow 150°C, 4°C min $^{-1}$; carrier gas, helium, 2.0 mL min $^{-1}$. Peaks: 1, nitrous oxide; 2, CFC-23; 3, CFC-13B1; 4, CFC-32; 5, CFC-115; 6, CFC-12; 7, CFC-125; 8, CFC-143a; 9, CFC-22; 10, CFC-134a; 11, chloromethane; 12, CFC-12B1; 13, CFC-114; 14, CFC 152a; 15, CFC-142b; 16, CFC-124; 17, bromomethane; 18, CFC-11; 19, dichloromethane; 20, CFC-141b; 21, CFC-123; 22, trichloromethane.

The selectivity of silica for separation of volatile halogenated hydrocarbons like the CFCs, is very specific. Unlike alumina, the CFCs do not decompose or react on silica, which makes their quantification possible at low levels (Figure 13). The low catalytic activity is also important for the analysis of pentadienes. On alumina these compounds polymerize due to the catalytic activity of the surface, while on silica these compounds elute as symmetrical peaks.

One of the key benefits of deactivated silica as an adsorbent is a more reproducible retention behaviour in the presence of water. Although water is retained by silica, the water will elute from the column and the influence on retention is small. Because of this, samples containing moisture can be analysed at lower temperatures. This is especially important if isothermal or fast analysis conditions are required, as in a plant analyser.

Metal PLOT Columns

The maximum temperature of polyimide-coated fused silica columns is limited to *c.* 350°C owing to

the stability of the polyimide protective outer coating. For higher temperatures a more stable tubing material is required. Metal capillary columns would be ideal but are very active. Several companies have been successful in deactivating metal to make it almost as inert as fused silica, and these deactivated metal columns have been successfully coated with alumina adsorbents, molecular sieves and 100% divinylbenzene porous polymers.

In comparison with fused silica columns, the metal column provides higher mechanical stability and offers, therefore, better mechanical reliability. Besides the high temperature capability, metal columns are especially applicable to process monitoring, on-line analysis and portable instrumentation.

Conclusion

Although it is likely that gas-solid chromatography will always represent something of a niche market in the gas chromatographic field as a whole, it is nevertheless of vital importance, particularly for gas analysis.

In the field of gas analysis, adsorbents offer the possibility of very selective separations that depend on the geometry of the molecules to be separated rather than the more generalized solubility mechanisms acting in gas-liquid chromatography. It should be theoretically possible to design adsorbents for particular separations. In the branch of liquid chromatography known as affinity chromatography, for example, it is already possible to manufacture stationary phases of exquisite specificity. An analogous approach might be possible in gas-solid chromatography and considerable work is in progress on the preparation and properties of molecular sieves with different dimensions to the well-established materials.

Headspace Gas Chromatography

Introduction

The term ‘headspace analysis’ was first applied to the analysis of gases in sealed cans and was later applied to the general analysis of vapours in contact with the sample from which they come. Gas chromatography was the technique of choice for this type of analysis; the combination is therefore called *headspace-gas chromatography* (HS-GC).

For quantitative analysis calibration of the volatiles in the vapour is necessary. This is achieved preferably, but not necessarily, in a state of equilibrium. To reach this state the sample is placed in a glass vial and thermostatted. When equilibrium is achieved, an aliquot of the gas phase above the sample is rapidly transferred onto the GC column. The term *equilibrium HS-GC* is commonly used for this sampling technique. However, since under certain circumstances calibration for quantitative analysis may also be performed in a nonequilibrium system, the term *static HS-GC* is more appropriate to distinguish this sampling technique from the so-called *dynamic HS-GC* techniques. In dynamic HS-GC analysis, the volatile compounds are stripped off completely from the sample by a continuous flow of an inert gas. This takes some time and the continuously delivered volatiles need to be concentrated in a trap, either by absorption or by cold trapping. The trapped compounds are released from the trap by thermal desorption and transferred to the gas chromatograph. This

technique, also known as *purge and trap*, is thus an off-line procedure, in contrast to the static headspace technique, where the headspace gas is transferred directly and on-line to the gas chromatograph. Thermal desorption is also used for sample transfer with a technique called *solid-phase microextraction* (SPME), where a thin rod or a small fibre, coated with a nonvolatile liquid phase, is inserted into a liquid sample or into the gas space of a headspace vial. The volatile compounds in the headspace are absorbed into the liquid-phase coating. After transfer into the heated injector of a gas chromatograph, the trapped compounds are released by thermal desorption. Off-line techniques, dynamic HS-GC and SPME are not discussed here, but all the important considerations regarding sample properties, such as matrix effects, necessary equilibration time, diffusion processes and sampling pretreatment, are common to all headspace techniques.

Fundamentals of Static HS-GC

The theory of static HS-GC is best explained using the example of a liquid sample present in a closed vial, as shown in **Figure 1**. The volatile analyte present in the liquid sample will evaporate into the gas phase until the concentration in both phases (C_s and C_g) remain constant. Equilibrium is achieved by diffusion from the sample into the gas phase and vice versa. The equilibrium constant is called the partition coefficient (K), and can be split into the mass ratio (k) and the phase ratio (β).

The aim of every quantitative analysis is the determination of the original concentration of the analyte (C_0) in the sample. The peak area (A) in a headspace

Figure 1 A headspace vial containing a liquid sample with a volatile analyte. Concentrations of the volatile analyte, C_G in the gas phase, C_S in the liquid phase; mass of the volatile analyte, W_G in the gas phase, W_S in the liquid phase; V_G , volume of the gas phase; V_S , volume of the liquid sample; K , partition coefficient; k , mass ratio; β , phase ratio.

chromatogram is proportional to the gas-phase concentration ($A \propto C_G$) and depends on the phase ratio (β). However, it depends not only on the sample volume (V_S), but also on the partition coefficient (K), as described by eqn [1]. This is the key relationship for static HS-GC:

$$C_G = \frac{C_0}{K + (V_G/V_S)} = \frac{C_0}{K + \beta} \quad [1]$$

The partition coefficient depends on both the temperature and volume. These two parameters strongly influence headspace sensitivity and are conditions that can easily be selected by the operator.

Sensitivity of Static HS-GC

Influence of Sample Volume and Temperature on Headspace Sensitivity

The sample volume (V_S) is included in the phase ratio (β) in eqn [1], but its influence on headspace sensitivity is not independent of the partition coefficient (K). The latter can vary widely from practically zero in the case of a gas sample up to several thousands, where the applicability of HS-GC ends. The phase ratio (β), and thus the influence of the sample volume, does not generally span such a wide range. For example, a 1 mL sample in a 10 mL vial has a phase ratio of 9, while with a sample volume of 5 mL the phase ratio decreases to 1.

Whether or not this causes an increase in the resulting gas concentration, and thus of the resulting peak area, depends mainly on the partition coefficient. In the case of a high partition coefficient ($K >$

100, e.g. ethanol in water), a change in the phase ratio from 1 to 5 will barely influence headspace sensitivity; in contrast, where the partition coefficient is very small the sensitivity increases in proportion to the sample volume (e.g. *n*-hexane in water at 50°C). This result may be surprising since it differs so much from normal GC analysis, where peak areas increase with increasing volumes of injected sample.

The vapour pressure of a compound increases exponentially with temperature. One would therefore expect a similar increase in the volatility, and thus enhanced sensitivity for a headspace compound. Again, however, there is a dependence on the partition coefficient. In the case of nonvolatile compound ($K \rightarrow \infty$), a higher temperature will not alter its nonvolatility. In the case of a highly volatile compound ($K \rightarrow 0$, already at room temperature), the temperature will not affect the headspace sensitivity either, because in this case nearly all of the compound is already present in the gas phase. Headspace samples generally fall between these two extremes. Table 1 gives typical values of partition coefficients at three temperatures for three compounds with a small (tetrachloroethylene), a medium (ethyl acetate) and a high (ethanol) partition coefficient.

Sensitivity Enhancement by Matrix Modification

The partition coefficient can be altered by modifying the sample matrix. A common technique is the use of the *salting-out* effect. For aqueous samples with a high partition coefficient (e.g. ethanol in water), the addition of salt may enhance the sensitivity by up to a factor of 10. Again, the result depends on the value of the partition coefficient. In the case of a highly volatile compound ($K \rightarrow 0$), where nearly all of the analyte is already present in the gas phase, the sensitivity will not improve.

A similar effect is achieved with a sample containing a nonpolar volatile compound dissolved in a water-miscible organic solvent, such as dimethylacetamide, dimethylformamide, etc. If water is added to this solution, the solubility of the nonpolar compound will decrease and its volatility will increase.

Table 1 Partition coefficients (K) in water–air equilibrium system

Compound	Temperature		
	40°C	60°C	80°C
Tetrachloroethylene	1.5	1.3	0.9
Ethyl acetate	62.4	29.3	17.5
Ethanol	1355	511	216

Sensitivity Enhancement by Modifying the Volatile Analyte

Polar compounds, particularly those with an active hydrogen (alcohols, phenols, acids, amines, etc.), usually have low volatility as a result of intermolecular interaction with the polar matrix through hydrogen bond formation. However the reactivity of the active hydrogen can be used to prepare less polar derivatives with better volatility and lower solubility. Simple reactions are preferred, such as esterification, transesterification, acetylation, etc., which are carried out in the headspace vial during the equilibrium time. An advantage of HS-GC is that the reaction products are less polar and more volatile, thus shifting the equilibrium of the chemical reaction towards completeness.

Instrumentation for Headspace Sampling

All the devices that are commonly used for gas sampling may be applied to headspace analysis, including gas-tight syringes and gas-sampling valves. A particular problem in HS-GC is the internal pressure in the headspace vial that is generated during thermostating at elevated temperature, represented by the sum of the partial vapour pressures of all the volatile compounds present, including water (since most samples contain some water). The vial must therefore be closed by a septum (preferably lined with polytetrafluoroethylene) (PTFE) and crimp-capped pressure-tight by an aluminium cap. This internal pressure may cause problems with sample loss during sample transfer with a gas syringe if it is not equipped with a pressure-tight valve. So that they can operate independently of the internal vial pressure, most automated headspace samplers surmount this problem by pressurizing the vial up to a certain pressure level

above the original pressure prior to sample transfer. Although it is not possible here to describe the various commercially available instruments in detail, the common principle is shown schematically in **Figure 2**.

Inert carrier gas enters the gas chromatograph through valve V and branches before the column. Part of the gas is directed to the sampling needle N. If this needle penetrates the septum, carrier gas flows into the vial and pressurizes it, usually up to the column head pressure, but any other pressure may be applied. Sample transfer is subsequently performed by closing valve V for a short time (usually few seconds), thus disconnecting the gas supply. The pressurized headspace gas in the vial expands either through the sample loop of a gas-sampling valve to atmosphere or directly onto the column. This on-column headspace sampling (also known as balanced pressure sampling) has the advantage that no headspace gas is wasted by unnecessary expansion to atmosphere, allowing the application of cryofocusing enrichment techniques. The actual volume of the headspace gas and the amount of analyte in it can be calculated from the transfer time (seconds) during which valve V is closed and from the volume flow rate (mL s^{-1}) at the column head.

The carrier gas flow rate in a capillary column is much lower than in a packed column, and therefore a much smaller volume of the headspace gas is introduced during the same sampling time. The resulting lower sensitivity can be circumvented by an increased sampling time, provided the accompanying band-broadening is suppressed by the technique of cryofocusing (also called cryogenic trapping or cold trapping). The normal admissible sample volume in a capillary column is about 50–200 μL , which is only 1% of the usually available volume of 5–20 mL headspace gas in the vial. With this technique of splitless on-column headspace sampling it is possible to

Figure 2 Principle of headspace sampling by either direct on-column sampling or by pressure/loop-filling with previous pressurization of the headspace vial.

Figure 3 Principle of cryogenic headspace trapping with splitless on-column headspace sampling.

extend the sample transfer time from a few seconds up to several minutes with an accompanying increase in the headspace gas volume and sensitivity.

In the automated headspace sampler shown in **Figure 3** the cryotrap is placed in the oven of the gas chromatograph. The cryotrap is essentially a short piece of fused silica capillary column, either the first coil of the separation capillary or a corresponding short piece of a different capillary column. The latter, called here the cryocapillary column, is coated, preferably with dimethylsilicone, a substance with a glass transition temperature of -114°C . Dimethylsilicone works as a stationary phase even at that low temperature, dissolving the compound in the liquid phase rather than just trapping by condensation. This cryocapillary column may then be connected to any other type of a capillary column by a butt connector. The cryocapillary column is jacketed by a 0.5 m PTFE tube, through which cold nitrogen gas flows outside the capillary column but in the opposite direction to the flow of warm carrier gas inside. The volatile analytes are trapped along the resulting strong temperature gradient in the capillary column. When sample transfer is interrupted by opening valve V, the flow of cooling gas is also stopped. A very rapid desorption is then achieved with a sharp starting band profile, since the warm carrier gas inside the capillary now heats the low mass fused silica capillary rapidly up to the oven temperature. The nitrogen gas used for cooling is produced outside the gas chromatograph by passing the nitrogen through a metal coil in a cooling bath, for example through liquid nitrogen. The sampling time and thus the headspace gas volume is restricted to only a few minutes before ice forms from the water sample, causing a blockage. However, a remarkable improvement

of the sensitivity compared to the usual injection times of a few seconds is obtained. Injection times of up to 10 min can be obtained by placing in the sample transfer line a small trap containing lithium chloride on a solid support in a small tube. This water trap (optional and not shown in **Figure 3**) is regenerated after each analysis by heating to 200°C and backflushing the released water. The chromatogram in **Figure 4** gives an example of the headspace analysis of low ppb concentrations of volatile aromatic hydrocarbons (BTEX) in a water sample by cryo-HS-GC.

Quantitative Headspace Analysis

Any quantitative method used for HS-GC has to take into account the influence of the sample matrix. The neat matrix should be available to prepare calibration standards, except for gas samples or if the composition of the gas phase only has to be determined, as in aroma research. The calibration techniques of *standard addition* or *multiple headspace extraction* (MHE) do not need the pure sample matrix, as opposed to internal or external standard calibration, which do. A neat matrix is also not necessary if the volatiles are completely evaporated into the gas phase. This effect can be achieved by reducing the sample size in the vial to a very small amount – say 10–15 mg. The determination of phenols in a resin-coated copper wire is shown in **Figure 5** as an example for this technique, called *total vaporization* (TVT), or sometimes *full evaporation* (FET). The small amount of 10 mg in a 22.3 mL vial gives a phase ratio (β) of >2000 and thus a nearly exhaustive extraction, allowing calibration by an external vapour standard, prepared also by TVT.

Figure 4 Determination of volatile aromatic hydrocarbons (BTX) in water by cryo-HS-GC with FID. Perkin-Elmer AutoSystem, HS40 Automatic Headspace Sampler with cryoaccessory and water trap; cryocolumn: 0.8 m \times 0.32 mm i.d. fused silica capillary, coated with immobilized dimethylsilicone, film thickness 1 μ m; separation column: 60 m \times 0.25 mm i.d., Stabilwax (Restek), film thickness 0.25 μ m; temperature program: 40°C (1 min), 20°C min⁻¹, 65°C (4 min), 10°C min⁻¹, 100°C (8 min); carrier gas: He, 210 kPa; sampling: splitless 3 min; sample: 10 mL, equilibrated 35 min with shaker at +80°C. Components: 1 μ g L⁻¹ each of: 1, benzene; 2, toluene; 3, ethylbenzene; 4, *p*-xylene; 5, *m*-xylene; 6, *o*-xylene.

Liquid samples are also accessible to this technique. In the case of solutions it is feasible to reduce the volume such that even the solvent evaporates completely at the appropriate temperature of the vial, without forming a condensed liquid phase, while nonvolatile sample constituents (e.g. salt in a wastewater sample or the polymer in the case of the polymer emulsion) remain as a dry residue in the vial. The admissible sample volume depends on the molar volume of the solvent and is typically about 15 μ L in a 20 mL headspace vial. The vial is used here just as the glass liner in a normal GC injector, which retains the nonvolatile residue. An automated headspace sampler is thus used in a similar manner to an autosampler but with disposable injectors. This technique is very useful for samples that do not need the highest sensitivity; time-consuming equilibration is not required here and the volatile fraction of the sample is completely present in the gas phase. No matrix influence has to be calibrated and the quantitative analysis therefore is as simple as in normal GC.

However, HS-GC is, in general, applied to determine the volatile fraction of a sample and, except for normalization (which makes hardly any sense here),

all other calibration methods may be applied. The principles behind these calibration methods for liquid samples are briefly discussed here; solid samples are treated below.

The use of an internal standard is the most popular calibration method in gas chromatography, but has some limitations for headspace analysis. A detector response factor must be determined, but if applied to HS-GC, matrix effects must also be included. A neat matrix must therefore be available to prepare a calibration standard. Such a calibration matrix may be prepared from the sample by stripping off all the volatiles first and spiking the remaining sample with the compounds to be analysed. Sometimes also an artificial matrix may be prepared (e.g. 11% ethanol in water, if flavour compounds in a wine sample are to be quantitated). If the sample is sufficiently concentrated it may be diluted with a (high boiling) solvent. This solvent then becomes a surrogate sample matrix because compounds below a concentration of about 1% usually have no measurable matrix effect. Sometimes an internal standard is added only to compensate for slight variations of the sample matrix. Since matrix effects are caused by intermolecular interaction, the internal standard should be of the same chemical nature as the compounds to be determined. For example, in blood alcohol analysis, another alcohol (*t*-butanol or *n*-propanol) is used. The main purpose of an internal standard calibration is to

Figure 5 Determination of phenols from a resin-coated wire by TVT. Perkin-Elmer AutoSystem, HS40 Automatic Headspace Sampler; column: 25 m \times 0.32 mm i.d. fused silica capillary, coated with immobilized poly(14% cyanopropylphenyl/86% dimethylsiloxane), film thickness 1 μ m; temperature programme: 150°C (10 min), 10°C min⁻¹, 220°C; carrier gas: He, 118 kPa; split sampling: split flow 16 mL min⁻¹, sampling time: 0.08 min; detector: flame ionization (FID); headspace conditions: pressurizing gas (He), 145 kPa; needle and transfer line temperature, 200°C; sample, 10 mg, equilibrated 35 min at 210°C. Components: 1, phenol, 2.4% (w/w); 2, *o*-cresol; 3, 2,3-dimethylphenol; 4, *m*-cresol + *p*-cresol; 5, 2,4-dimethylphenol + 2,5-dimethylphenol; 6, 3,4-dimethylphenol.

compensate for poor sampling reproducibility. This may still be a problem with manual syringe injection, but not with autosamplers, whose sampling precision is in general <1%.

External standard calibration also requires the neat matrix for preparing a standard sample, but permits simpler sample handling since no additional compounds need to be added to each sample. The sample is placed in the vial, which is closed immediately. The vial remains closed until an aliquot is withdrawn for analysis, thus guaranteeing sample integrity. This is the most simple calibration technique.

If a neat matrix sample is not available, then the method of standard addition is the most universal calibration method. Calibration is carried out with each analyte and no response factor is necessary. The added compound suffers the same matrix effects as the original sample. Standard addition needs at least two analyses to be carried out for each sample, but the increased time required is less of a disadvantage if an automated headspace sampler is used. Several repeated determinations are necessary in any case if statistical confirmation of the analytical result is required, preferably by multilevel addition with linear regression calculation of the result.

Another technique that does not need the neat sample matrix uses repeated gas extractions. This is similar to the dynamic headspace technique, with the difference that the volatiles are removed by a stepwise gas extraction rather than continuously. This technique of multiple headspace extraction (MHE) can be carried out with the same instrumentation as used for static HS-GC. With the technique of direct on-column headspace sampling it is carried out in such a way that the vial is first pressurized as described above. When sample injection is stopped, the vial is pressurized again, but its gas phase subsequently vented to the atmosphere. Thus most of the headspace gas is removed, depending on the ratio of headspace pressure (P_H) to atmospheric pressure (P_A). The equilibrium is disturbed, since the gas-phase concentration (C_G) has dropped. The equilibrium has to be re-established by additional evaporation of the analyte and the next analysis now gives a smaller peak, the difference corresponding to the amount of the analyte vented.

This stepwise gas extraction analysis is repeated several times and a series of exponentially decreasing peak areas is obtained. The logarithm of the peak area is plotted against the number of extractions, to give a straight line that allows the application of linear regression to obtain the sum of the area values as the sum of a geometric progression. It is not necessary to proceed until exhaustive extraction is achieved, since a minimum of two area values allows

such a linear regression calculation. The total area obtained corresponds to the total amount of the analyte in the sample and this value is independent of the matrix influence. The resulting area total must be calibrated, but for this purpose the matrix is not required, and even a vapour standard, prepared very conveniently by the TVT technique, can be used as an external standard. In practice it is the gas phase concentrations in both vials that are compared. A correction for the sample volume is therefore necessary, since the volume of the gas phase in the vial containing the sample differs by the sample volume in comparison to the 'empty' calibration vial, and so does the corresponding concentration in the gas phase.

Classification of Sample Types

All of the calibration techniques described above may be applied to liquid samples with no particular problems. Sometimes it is necessary to dilute very viscous samples or to reduce long equilibration times by using a shaker. Liquid samples also show a wide range of linear relationships between concentration in the sample and peak area – the headspace linearity. Solid samples can also be analysed by HS-GC, but only if they behave as a partition system, similar to liquid samples, owing to inherent calibration problems. However, most solid samples behave as a nonlinear adsorbent. Additional problems are caused by slow diffusion in a solid matrix; size, porosity and specific surface of solid samples are therefore very important parameters. Bulky solid samples are not amenable to HS-GC at all unless they are pulverized, for example by freeze grinding, with loss of the volatiles avoided by chilling the sample with liquid nitrogen or dry ice. There are many problems to be taken into account and most techniques for solid samples try to establish a partition system, which can then be treated like a liquid sample.

Polymers and plastic materials often behave as partition systems if heated above the glass transition temperature. A classical example is the determination of vinyl chloride monomer in a polyvinyl chloride (PVC) resin above the glass transition temperature of 85°C. Such solid samples can be handled as a quasiliquid sample with all types of calibration techniques. Even the technique of standard addition may be applied, because the analyte may be added to the gas phase and not necessarily into the sample using the existing equilibrium system to achieve homogeneous partitioning from both directions. However, considering the variety of plastic materials – pure resins, preforms, copolymers, complex mixtures with all type of additives and finished products – any new solid sample has to be checked carefully for this

property. An example for a systematic approach to develop a suitable quantitative method for a solid sample is given below.

The most common procedure for headspace analysis of solids is the *solution approach*, where the sample is dissolved in an appropriate high boiling solvent, which is eluted late in the chromatogram and may be removed by column backflushing. The disadvantage is the reduced sensitivity due to the dissolution.

Insoluble samples can often be handled as a suspension in water or an organic solvent, using the displacement effect of the solvent. This *suspension approach* works well where the analytes are superficially adsorbed. It is obvious that the samples should be a powder rather than a bulky material, to provide the necessary large surface. Calibration in this case is straightforward by using an external standard in the same solvent. The insoluble solid sample remains as a slurry in the headspace vial and causes no matrix effect. A smaller amount of solvent is sufficient here to dissolve only the displaced volatiles, compared to the solution approach where the whole sample must be dissolved. But the resulting smaller dilution effect may be even further minimized by reducing the volume of the high boiling solvent such that only the surface of the sample is wetted by the solvent, which then works as a surface modifier. This *surface modification* technique provides a homoge-

neous surface with constant adsorptivity. In this way a much better sensitivity can be achieved owing to the smaller amount of such a liquid displacer. The absence of any residual adsorptivity, however, has to be confirmed, e.g. by the MHE technique. In this case the solid sample with its homogeneous surface behaves like a partition system, where the partition coefficient remains constant over a wide range.

Practical Example: Determination of Ethylene Oxide in a PVC Tube

From the foregoing discussion it is apparent that there are several possible ways to carry out a quantitative headspace analysis. A systematic approach to develop the most suitable calibration technique is therefore desirable. This is illustrated by the following example of the determination of ethylene oxide (EO) in a sterilized PVC tube. Ethylene oxide is widely used for sterilization, but due to its toxicity the residual concentration must be carefully controlled down to a safe limit (e.g. 1 ppm). This example covers several of the aspects discussed above. Since PVC tubing is a solid sample, the solution approach was naturally the first choice. The sample was dissolved in dimethylacetamide and calibration was by multilevel standard addition (see Figure 6), resulting in an EO concentration of 19.95 ppm with a precision as expressed by the correlation coefficient of 0.9961.

Figure 6 Determination of EO in a sterilized PVC tube by standard addition calibration (STA) and by multiple headspace extraction (MHE). Gas chromatographic conditions: Perkin-Elmer SIGMA 2000, HS100 Automatic Headspace Sampler; 2 m × 3.2 mm stainless steel column, packed with Chromosorb 101, 80/100 mesh; temperature programme: 100°C (7.5 min), 15°C min⁻¹, 200°C; detector: FID; carrier gas: He, 20 mL min⁻¹; calibration standard: aqueous solution of EO (10.3 µg µL⁻¹).

(A) STA. Sample preparation: 1 g PVC tube, dissolved in 2 mL dimethyl acetamide, equilibrated 90 min at 90°C; calibration by adding 10, 20 and 30 µL of the calibration standard; result: 19.95 µg g⁻¹ EO, regression coefficient $r = 0.9961$.

(B) MHE. Sample preparation: 1 g PVC tube, cut in pieces of 3 mm × 4 mm, 1 mm thick, equilibrated as above; calibration by external vapour standard, prepared by TVT of 8 µL; total area counts from sample analysis: 258 464, from calibration standard: 104 132; result: 19.53 µg g⁻¹ EO; regression coefficients: sample (S), $r = -0.99914$; calibration standard (C), $r = -0.99990$.

Due to problems with solvent impurities and also to achieve a better sensitivity, a solvent-free method was expected to be superior. A six-step MHE procedure with the sliced solid sample was calibrated with a five-step MHE of an external vapour standard (see Figure 6) and after the necessary volume correction a nearly identical concentration of 19.53 ppm was obtained, but now with a four-times higher sensitivity. Also the precision was better, as expressed by the linear regression coefficients of -0.99914 for the sample and -0.99990 for the calibration standard. This allowed reduction of the MHE procedure to three steps, but still with a linear regression calculation, and a two-step procedure is sufficient if the highest precision is not required.

From these good results some more conclusions may be drawn to simplify the analysis further. The good linearity over the whole working range indicated that the solid PVC matrix was behaving as a partition system; this conclusion allowed the application of standard addition calibration in the form of gas-phase addition. Even the use of an internal standard appears feasible, since from a successful gas-phase addition it can be concluded not only that EO partitions between both phases, but that any other compound will do the same, provided it is similar in its chemical properties (e.g. dimethyl ether). As discussed above, a calibration factor has to be determined first, which comprises not only the differences in the detector response but also the different solubilities (partition coefficients) in the PVC matrix. For this example it is no problem to obtain a PVC tube without any EO in it.

Taking into account all these possibilities, the final decision as to what is a suitable calibration technique may depend on other considerations such as the simplicity of sample handling or the sample throughput in an automated headspace sampler. For example, the standard addition calibration needs a series of vials to be subsequently analysed, thus occupying the corresponding number of places in the turntable of an autosampler, while for the MHE procedure the determinations are all carried out from the same vial and the sample throughput in an autosampler will therefore not be affected. On the other hand, the addition of an internal standard to every sample is tedious and prone to errors, particularly if pipettes are used to transfer solutions with highly volatile compounds.

Applications

Static HS-GC relies in general on a thermodynamically controlled equilibrium. It is natural therefore that it has been applied not only for analytical purposes, but also for the determination of physico-

Table 2 Selected analytical applications of static headspace gas chromatography

-
- Residual solvents in pharmaceuticals, food, packing material, aluminium and plastic films
 - Monomers in polymer resins, emulsions and finished products
 - Ethylene oxide in sterilized clinical material
 - Volatile aromatic and halogenated hydrocarbons in air, water and soil
 - Flavour compounds in beverages and spices
 - Odour compounds in foodstuffs, herbs, flowers and perfumes
 - Rancidity of fat and oil
 - Water content in any type of liquid and solid sample as an alternative to KF titration
 - Dithiocarbamates, degraded to CS₂, in vegetables, fruits and flowers
 - Analysis of beverages for diketones (in beer), sulfur compounds, alcohols, esters, aldehydes and acids
 - Ethanol in blood, food and beverages
 - Volatile fermentation products from anaerobic bacteria
-

chemical data such as vapour pressures, partition coefficients, activity coefficients and related mixing functions (energies and enthalpies of mixing), adsorption isotherms, and also for kinetic measurements such as the determination of reaction constants and the rate of release of volatile compounds from solid material. Table 2 lists some important analytical applications.

Introduction

Gas chromatography (GC) is generally believed to be restricted to the analysis of 'volatiles' and is less applicable to the analysis of so-called 'heavy' compounds. The introduction of persilylated glass and fused silica columns, of thermostable stationary phases and of non-discriminative injection devices in capillary GC (CGC) have made the definitions of 'volatile' and 'heavy' very flexible.

High temperature GC (HTCGC) was developed in the 1980s as a result of work carried out by Grob, Geeraert and Sandra, Trestianu *et al.*, Lipsky and Duffy, and Blum and Aichholz (see Further Reading). Although HTCGC was initially not accepted as a 'robust' analytical technique for the analysis of high molecular weight compounds, in recent years several research groups have demonstrated the capabilities of HTCGC for the analysis of hydrocarbons with carbon numbers in excess of 130 (simulated distillation), of lipid compounds, of emulsifiers, of detergents, of polymer additives, of oligosaccharides, of porphyrins and of many more solutes.

Defining a temperature in HTCGC is not straightforward but it is now generally accepted that 420°C is the maximum allowable column temperature limit in practice. Applications at higher column temperatures have been carried out but, with the exception of hydrocarbons, most organic compounds do not withstand temperatures higher than 420°C. Moreover, the maximum allowable operating temperatures (MAOT) of the stationary phases applied in HTCGC are all lower than 450°C. A prerequisite in HTCGC is that the solutes to be analysed are thermally stable and can be volatilized. The thermal stability of organic compounds depends not only on their nature, but also on the activity of the environment to which they are subjected and on the thermal stress given to the solutes. HTCGC is nowadays performed in a completely inert system, i.e. high purity carrier gas, dedicated and purified stationary phases, fused silica columns with less than 0.1 ppm trace metals and specially deactivated, etc. Moreover, thermal stress is reduced by applying cool on-column (COC) or programmed temperature vaporizing (PTV) injection. Lipids may serve as a good illustration. When oils or

fats are used in food preparation, they decompose (formation of volatiles) or polymerize (formation of dimers, trimers, etc.) as a function of time, which makes them no longer useful for cooking. These alterations are caused by the presence of water and oxygen. When heated under inert conditions, however, fats and oils are stable and evaporate. **Figure 1** shows the thermogravimetric profiles for triolein with a molecular mass of 886 Da under a stream of pure nitrogen (A) and of air (B).

In present state-of-the-art HTCGC, the systems are operated under the circumstances shown in curve A. Volatility, on the other hand, is related to the vapour pressure (boiling point) of the compounds. Polydimethylsiloxanes with molecular masses as high as 5000 Da are volatile enough to be analysed by HTCGC, whereas low molecular weight (oligo)saccharides, for example, are not volatile at all. This is because of the polarity of the functional groups. Derivatization is often employed to impart volatility and to yield a thermostable product, thereby also improving chromatographic performance and peak shapes. Silylation, alkylation and acylation are used to modify the active hydrogen in compounds containing -OH, -COOH, and -NH₂ functionalities.

HTCGC is a reliable analytical method if a number of prerequisites are fulfilled. The different aspects of the technique are discussed and the potential illustrated with a number of relevant applications.

Instrumentation for HTCGC

Columns and Stationary Phases

Different support materials have been applied in HTCGC. Leached and deactivated borosilicate glass provides an excellent surface for high temperature

Figure 1 Thermogravimetric analysis of triolein. Ramp from 20 to 500°C at 5°C min⁻¹. (A) pure nitrogen, (B) air.

work. The surface can be coated with different high temperature phases for applications up to 450°C. Glass columns are, however, not really accepted for routine work as they break easily and are difficult to handle. Nevertheless, some laboratories still use glass columns because of their excellent performance for specific applications (Blum and Aichholz). Leached and persilylated fused silica is nowadays mostly applied. The outer polyimide coating of classical fused silica open tubular (FSOT) columns withstands temperatures up to 400°C, thus covering most of the applications of HTCGC. To increase the lifetime of the columns, they are often wrapped in aluminium foil to avoid contact with oxygen which initiates polyimide decomposition. Aluminium-clad fused silica columns have been introduced for applications up to 450°C. Because of the different expansion coefficients of fused silica and aluminium, the columns can become brittle under continuous heating and cooling conditions. An excellent alternative to glass, polyimide-coated fused silica and aluminium-clad fused silica columns are the recently introduced metal columns for which the active surface has been passivated, for example with a thin layer of fused silica. Silcosteel and Ultimet capillary columns for high temperature work are commercially available. The suppliers both make special columns to perform simulated distillation by GC according to ASTM method D 2887.

A large number of stationary phases have been synthesized for HTCGC. The group of W. Blum has been very active in this respect. Their HTCGC experiments, including the synthesis of the phases and the coating of capillary columns, are summarized in an excellent book. The three phases most often applied in HTCGC are methylsilicone, diphenyldimethylsilicone with phenyl contents varying between 5% and 65% and a carborane-modified methylsilicone. The main reason for this is that high temperature columns with these phases are commercially available. The phases are OH-terminated and immobilization by polycondensation takes place at high temperatures after coating. This increases thermal stability and makes the columns solvent resistant.

Inlet Systems

Different injection devices for CGC have been developed over the years, but only two are applicable in HTCGC, namely COC and PTV injection. With both devices the sample can be introduced at low temperatures avoiding solute alteration or discrimination. For cool on-column injection, an injector device with an elongated secondary cooling tube is advised because this enables high oven temperatures to be used. A hot injector such as a split/splitless injector, has

been used to analyse quaternary ammonium salts. At injection temperatures above 360°C the salts are demethylated and the resulting tertiary amines can be analysed by HTCGC. Standard deviations are, however, quite high.

Carrier Gas and Mode of Delivery

Carrier gases with fast diffusion properties, i.e. hydrogen and helium, should be used. When the viscosity is also taken into account, namely $1990 \times 10^{-7} \text{ g cm}^{-1} \text{ s}^{-1}$ for helium versus $840 \times 10^{-7} \text{ g cm}^{-1} \text{ s}^{-1}$ for hydrogen, the performance of the latter is much better because the H vs. u plot at high temperatures is relatively flat whereas the plot for helium is much steeper. If, for safety reasons, hydrogen cylinders are not allowed, a hydrogen generator can offer a solution. The use of electronic pneumatic control (EPC) allows column flow to be maintained constant or even increased during a temperature programmed run, reducing elution times and temperatures. The effective operating range is thereby extended compared to constant pressure operation.

The features of EPC are illustrated with the analysis of some polymer additives (Table 1). The sample mixtures include a wide range of additive types, including polar and labile compounds as well as high molecular weight components. Irganox 1010 (compound 24) with molecular mass 1176 Da is particularly important here as an indicator of HTCGC capabilities in polymer analysis. The sample was analysed on a $25 \text{ m} \times 0.32 \text{ mm}$ i.d. fused silica open tubular column coated with a $0.17 \mu\text{m}$ film of methylsilicone. Hydrogen, delivered at a constant pressure (50 kPa) or in the constant flow mode, was the carrier gas. The column temperature was programmed from 80°C to 380°C at $10^\circ\text{C min}^{-1}$. Cool on-column injection was carried out in the oven track mode, which means that the injector and the column are then programmed at the same rate, and the FID detector was set at 380°C. The analysis shown in Figure 2 was done under isobaric conditions. The peak shapes and resolution are good but Irganox 1010 could not be eluted at 380°C. For the $25 \text{ m} \times 0.32 \text{ mm}$ i.d. column, 50 kPa hydrogen corresponds to 58 cm s^{-1} carrier gas velocity at the initial oven temperature (80°C) but only to 39 cm s^{-1} at the end of the run (380°C). For the chromatogram shown in Figure 3, the analysis was carried out in the constant flow mode. In this operating mode, the pressure is automatically increased (from 50 to 112 kPa in this case) as oven temperature increases, to maintain the initial flow rate throughout the run. Under these conditions, Irganox 1010 elutes at 32 min. The use of cool on-column injection with electronic pneumatic control also provides excellent repeatability in retention

times and quantitation. Average retention times and absolute peak areas for five runs are shown in Table 1. Relative standard deviations are within 0.04% for the retention times and 2% for the raw peak areas, even for the polar compounds such as erucamide and Irgaphos 168. This illustrates the robustness of HTCGC.

The combination of CGC with mass spectrometry (CGCMS) can also be used successfully for the analysis of these polymer additives. Helium was the carrier

gas in the GCMS combination and this had some consequences on the selection of the column. The column length was reduced to 12 m, the i.d. to 0.2 mm and the film thickness to 0.11 μ m. With helium at an inlet pressure of 10 kPa and operated in the constant flow mode, Irganox 1010 eluted at 39.5 min.

Detectors

The use of the universal flame ionization detector (FID) or selective detectors such as nitrogen-phos-

**Figure 2** HTCGC analysis of the polymer additives using constant pressure mode. Peak identifications are given in Table 1.

Figure 3 HTCGC analysis of the polymer additives using constant flow mode. Peak identifications are given in Table 1.

phorus detection (NPD) or electron-capture detection (ECD) does not pose any problem in HTCGC. Moreover, the spectroscopic techniques mass spectrometry (MS), atomic emission detection (AED) and inductively coupled plasma mass spectrometry (ICPMS) are compatible with HTCGC. As an illustration, Figure 4 shows the element-specific chromatograms for the phosphorus line at 178.1 nm (A) and the sulfur line at 181.4 nm (B) for the sample listed in Table 1 with the AED detector. The transfer line and cavity temperatures of the AED were set at 340°C. The other chromatographic conditions were very similar to those used for Figure 3.

Applications of HTCGC

In the framework of this contribution, it is impossible to review all applications of HTCGC. Some of the most relevant applications are detailed.

Hydrocarbons

HTCGC is nowadays intensively applied for the calculation of the true boiling point distribution of heavy petroleum products (simulated distillation or SIMDIS). In this type of analysis, high resolution is not wanted. The most desirable prerequisite the technique should fulfil is complete and quantitative elution. Hydrocarbons up to C_{130} elute quantitatively on short capillary columns coated with a thin film of methylsilicone.

Lipids

The qualitative and quantitative elucidation of glycerides is an important analysis in different fields, e.g. characterization of natural products, of food products, in lipid metabolism studies, bacterial identification, etc. A variety of techniques is routinely applied including liquid chromatography (LC), supercritical fluid chromatography (SFC) and HTCGC. Of these techniques, HTCGC provides the highest resolution in the shortest analysis time. The HTCGC analysis of a standard mixture of silylated mono-, di- and triglycerides is shown in Figure 5. The analysis was performed on a 12 m \times 0.32 mm i.d. \times 0.17 μ m methylsilicone column programmed from 80°C to 380°C at 15°C min. Hydrogen was the carrier gas at 65 cm s⁻¹ and both cool on-column and PTV injection could be applied.

Figure 5 Analysis of silylated mono (M)-, di(D)- and tri(T)-glycerides. P, palmitic acid; S, stearic acid.

It is often claimed that HTCGC yields erratic quantitative results for triglycerides because of decomposition. Problems can indeed be encountered with oils containing large amounts of highly unsaturated triglycerides such as trilinolenin (LnLnLn), which tend to polymerize and not to decompose. For quantification of such lipids, calibration is necessary. Most of the oils and fats, however, can be analysed perfectly well by HTCGC. On apolar columns of the methylsilicone type, triglycerides are separated according to the carbon number. On polarizable diphenyl (50–65%) dimethylsilicone phases, besides a carbon number separation, lipids are also separated according to the different combinations of saturated and unsaturated fatty acids in the triglycerides. **Figure 6** shows the analysis in 3 min of the lipids in palm oil. The diglycerides with carbon numbers 32 to 36 and the triglycerides from C46 to C56 were separated on a 5 m × 0.25 mm i.d. × 0.1 µm methylsilicone in a temperature programmed run from 290°C to 350°C at 30°C min⁻¹ applying cool on-column injection and with hydrogen as carrier gas at 103 kPa. **Figure 7** shows the analysis of inter-esterified cocoa butter on a poly(dimethyldiphenylsiloxene) column 25 m × 0.2 mm i.d. × 0.1 µm film. The sample was introduced via a PTV injector. Besides a carbon number separation, the triglycerides on this phase are also separated according to degree of unsaturation.

HTCGC is nowadays the method of choice in the chocolate industry to control the natural origin of cocoa butter and to elucidate the addition of cocoa butter equivalents and/or nut oils.

Detergents and Surfactants

Most of the non-ionic surfactants can be analysed by HTCGC. This is illustrated in **Figure 8** with the analysis of trimethylsilylated Triton X-100, an alkyl-phenol polyethoxylate, on a 10 m × 0.32 mm i.d. × 0.1 µm diphenyl (5%) dimethylsilicone column.

The temperature was programmed from 65°C to 200°C at 40°C min⁻¹ and then to 390°C at 8°C min⁻¹. Cool on-column injection was used. Helium was the carrier gas at 70 kPa. The relative standard deviation of retention times was lower than 0.1% and on raw peak areas lower than 0.7%. Another type of non-ionic surfactant is the polyethylene glycols (PEGs). HTCGC is able to analyse samples containing PEGs up to 1300 Da (PEG 1000).

Oligosaccharides

Oligosaccharides are thermally unstable and have to be derivatized into the well-known oxime-trimethylsilyl derivatives. The limits of HTCGC are illustrated in **Figure 9**. An oligosaccharide sample, obtained by hydrolysis of insulin extracted from *Cichorium intybus*, with DPs ranging from DP1 to DP12 could be analysed in approximately 30 min on a 10 m × 0.53 mm i.d. × 0.1 µm methylsilicone column. The degree of polymerization (DP) is the number of sugar units in the oligosaccharides. Both the pressure (50–200 kPa) and the temperature (100–430°C) were programmed to elute the high DP numbers. The analysis was performed on an aluminium-clad column. In this application resolution is sacrificed for speed of elution.

Figure 6 Fast carbon number separation of palm oil.

Emulsifiers

Organic substances added to food products to form emulsions are very complex mixtures. At present, there is no universal analytical method to elucidate the nature and origin of an emulsifier. Nevertheless,

Figure 7 Analysis of inter-esterified cocoa butter. P, palmitic acid; S, stearic acid; O, oleic acid.

Figure 8 HTCGC analysis of Triton X-100 as trimethylsilyl derivatives. Numbering: ethylene oxide (EO) units.

HTCGC allows the characterization of a large number of emulsifying mixtures. This is illustrated with the analysis of two commercially available emulsifiers: one based on sorbitol (**Figure 10A**) and one on lactic acid (**Figure 10B**). Both samples were analysed on an automated HTCGC instrument (HP 6890) equipped with a 13 m \times 0.32 mm i.d. \times 0.1 μ m methylsilicone column and a cool on-column injector. The silylated samples were injected in the oven track mode with an oven temperature programme from 70 to 370°C at 15°C min⁻¹. Hydrogen was the carrier gas at 25 kPa.

Miscellaneous

This overview of applications of HTCGC is far from complete and could be extended with the analysis of metal porphyrins in crude oils (geomarkers), of tall oil components, of mycolic acids, of antifoam agents, of antibiotics, etc. The applied methodologies are, however, similar to those described for the other applications.

Conclusion

HTCGC is a powerful analytical method for the analysis of high molecular weight compounds. Instrumentation and columns are commercially available. For some applications, derivatization into stable volatile substances is required.

In HTCGC we cannot expect spectacular new developments because the thermal stability of the compounds being separated is the limiting factor. The MW range can be expanded a little by applying high speed columns, i.e. short lengths and small internal diameters. By reducing the residence time in the column, the thermal stress is reduced as well.

Figure 9 HTCGC analysis of an oligosaccharide sample using a temperature and pressure programme.

On the other hand, we will see more and more applications in the literature because CGC is always superior in terms of efficiency and speed of analysis compared

to the other separation methods. With state-of-the-art HTCGC a number of applications presently carried out with LC or SFC, can be done much better with GC.

High-Speed Gas Chromatography

A. Andrews, Ohio University, Athens, OH, USA

Copyright © 2000 Academic Press

Introduction

High speed gas chromatography (GC) has been the subject of an increasing number of papers in both journals and at conferences in recent years. These articles have progressed from concept papers mainly detailing the necessary instrumental modifications to the potential applications of high speed GC.

This article is focused on reported applications of what may be regarded as traditional high speed GC, i.e. short, wall-coated open tubular columns (generally of internal diameter (i.d.) <0.32 mm) operated at a higher than optimal carrier gas flow rate. The total chromatographic separation time is required to be less than 3–4 min. This eliminates some work on polychlorinated biphenyl separations where run times are approximately six times faster than conventional GC, but still take around 10 min. Other areas in high speed GC, such as rapid packed column separations, porous layer open tubular columns and the newly emerging imaging technique of solvating GC using packed columns will not be addressed. In addition, only those articles which specifically relate to the use of high speed GC for a particular analysis have been considered. The separation of a large number of compounds by high speed GC has been demonstrated in many research articles, but many of the mixtures separated are not specific to any particular problem or truly relevant to real world analysis.

High speed GC is still mainly an academic research technique. The number of published applications is small and review articles or books detailing these applications are nonexistent. For this reason this article draws mainly on journal papers.

High speed GC is not a new analysis technique. The first true high speed separations involving capillary columns were carried out nearly four decades ago by Desty. Although this clearly demonstrated that separations in seconds were possible, the instrumental demands that high speed GC makes upon the gas chromatograph made it unsuitable for general use at that time. In the following years several notable research groups around the world have made excellent progress both in solving some of the instrumental problems and in clarifying the theoretical considerations involved with high speed GC. In particular, the major contributions of Annino and Guiochon to theoretical developments and the research groups of

both Cramers and Sacks for instrumental advances deserve specific mention.

There are several reasons for this slow transfer of high speed GC from the research laboratory to the analytical laboratory. One is the reluctance of application laboratories to substitute a new untried procedure for a known analytical method, even when the new procedure offers major time savings. New methods frequently encounter this hurdle and as more literature reports on high speed GC applications appear, this barrier should slowly crumble.

Another barrier, which will be harder to overcome, is the problem of sample preparation. The advantages of a very fast chromatographic separation are negated if the sample preparation step takes an order of magnitude or more longer than the separation. Further basic research is required in the sample preparation area to bring these two stages closer inline with each other. The workers who have pioneered high speed GC research in the last decade are already incorporating faster sample preparation steps into their research and it is likely that the coming years will see the progress needed in this area.

To date, most high speed GC applications have been in the analysis of volatile organic chemicals (VOCs) in either air or water. Other applications include chlorinated pesticides, polyaromatic hydrocarbons (PAHs), and the use of high speed GC to determine solvent purity. Each of these areas will be considered in more detail below.

Volatile Organic Chemicals

Air

Near real-time results may be particularly beneficial for a system where a centrally located high speed gas chromatograph is connected to a network of sampling lines. The high speed GC analysis of VOCs must be able to detect compounds at and below regulatory levels, such as the threshold limit value (TLV).

Original work utilized a valve loop system for sampling, but the use of mechanical valves may be a problem for an automated system. Valves may require periodic maintenance, or may change the sample through interaction with valve surfaces. In addition, changing the sample size requires either changing the loop or the use of several loop cycles. Ice formation which may plug the collection tube, resulting from water vapour in the air is another area of concern. However, studies to date have not shown this to be a problem.

Figure 1 Complete high speed GC system with direct atmospheric sample collection. T, Cold trap system; V, valves; R, restrictors; P, vacuum pump; I, atmospheric pressure source; C, separation column; G, gas source. Arrows show flow directions during sample collection. (Reproduced with permission from Akard and Sacks, 1994.)

An alternative approach to achieve the detection limits required is a technique termed cryointegration. In this method, VOCs from an air sample, usually contained in a sampling loop, are cryofocused in a liquid nitrogen-cooled metal tube. Thus, dilute samples can be preconcentrated prior to high speed analysis. Resistive heating of the metal tube is used to ensure a narrow injection plug compatible with high speed GC requirements. This has been incorporated with a reversed-flow sample collection system. **Figure 1** shows the complete high speed GC system for an air monitor using this type of set-up.

The vacuum pump pulls sample and carrier gas through the cryotrap for the sample collection period. This time period can be adjusted to allow for more or less sample to be collected as required. After collection, the sample is introduced on to the separation column by heating the metal cryotrap tube.

The positioning of the sample near the column end of the cryotrap reduces band broadening and the potential for sample decomposition. The decreased bandwidth leads to narrower, taller peaks, which in turn improve the limit of detection (LOD). Although water vapour in the sample condensing in the cryotrap is not a problem, water vapour from the flame ionization detector (FID) is. For this reason, a gas source attached midway through the separation column has been used to prevent water vapour from the detector reaching the cryotrap.

Figure 2 shows representative chromatograms obtained using gasbag samples. The sampling flow rate is constant and about 0.3 mL min^{-1} once steady-state flow is achieved. There is, of course, a trade-off between reducing the LOD and loss of real-time data as the sampling time increases.

Tables 1 and **2** show the limit of detection values obtained using the conventional loop system and the

reverse-flow collection system respectively. It can be seen that, as the sampling time increases with the cryointegration system, the LOD values approach those obtained using a fixed 1 mL loop. One would expect that further increases in sampling time would reduce the LOD even further. The disadvantage with further increases in sampling time is the loss of real-time information. These LOD values are already below regulatory or guideline concentrations such as the TLV and a further reduction in LOD would seem unnecessary.

Water

The apparatus used for VOC analysis in water by high speed GC is essentially the same as that used for the air analysis work. This is because, as sample preparation is conducted by a static headspace equi-

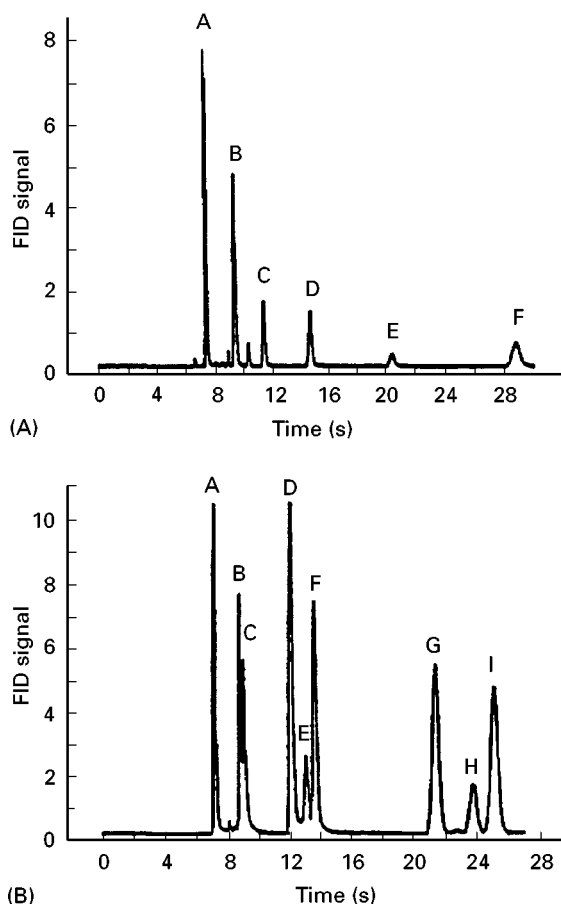

Figure 2 High speed chromatograms using gasbag samples and the reverse-flow collection instrument: (A) six-component mixture; (B) nine-component mixture. Peaks in (A) A, *n*-pentane; B, *n*-hexane; C, benzene; D, *n*-heptane; E, toluene; F, *n*-octane. Peaks in (B) A, *n*-hexane; B and C, isomers of 2-hexene; D, 1-heptene; E and F, isomers of 2-heptene; G, 1-octene; H and I, isomers of 2-octene. Table 1 Limits of detection and quantitation measured for 13 common organic compounds

Compound	LOD (p.p.b.v.)	LOQ (p.p.b.v.)
Pentane	2	7
Hexane	3	10
Heptane	4	13
Octane	5	17
Benzene	8	27
Toluene	2	7
<i>o</i> -Xylene	50	170
<i>m</i> -Xylene	1	3
Dichloromethane	< 1	< 3
Chloroform	< 1	< 3
Tetrachloroethylene	< 1	< 3
